Thyrotropin-receptor antibodies are a group of related immunoglobulins that bind to thyroid cell membranes at or near the TSH-receptor site. These antibodies are frequently found in the sera of patients with Graves' disease or other thyroid autoimmune disorders. In general, these antibodies demonstrate substantial heterogeneity; some cause thyroid stimulation, whereas others have no effect or decrease thyroid secretion by blocking the action of TSH. At present, these abnormal immunoglobulins cannot be differentiated by chemical or immunological methods; rather, their presence is demonstrated using radioreceptor assays or bioassays with cAMP as the endpoint.

The first indication that autoantibodies to the TSH receptor might play a role in the pathogenesis of Graves' disease came with the discovery of long-acting thyroid stimulator (LATS) in the serum of some patients. The estimation of LATS using in vivo bioassay is important historically.[67] In a modification of the LATS assay, the so-called *LATS protector assay,* antibody binding to a thyroid homogenate prevents the expected inhibition of the standard LATS response.[72] This indirect assay is more sensitive than the direct LATS assay, but is cumbersome and seldom used in laboratories today.

The direct radioreceptor assay assesses the capacity of immunoglobulins to inhibit the binding of labeled TSH to its receptors in human or animal thyroid membrane preparations. Such antibodies are usually designated *thyrotropin-binding inhibitory immunoglobulins* (TBII). In this method, originally described by Shewring and Rees-Smith,[182] detergent-solubilized porcine TSH receptors and ^{125}I-labeled TSH are used. The ability of a purified fraction of serum immunoglobulins to displace ^{125}I-labeled TSH from the receptors is measured.[16] This method, available as a commercial kit, detects more than 85% of patients with Graves' disease and requires only 2 to 3 hours to perform.[130] Normal immunoglobulin G concentrates do not produce significant displacement of labeled TSH from the TSH receptor (<10% inhibition). This method detects all TSH receptor antibodies but cannot distinguish whether the antibodies stimulate the TSH receptor to cause hyperthyroidism or block the TSH receptor to cause hypothyroidism. Measurement of TBII is mainly used in pregnant women with present or past Graves' disease to assess the risk of fetal or neonatal thyrotoxicosis occurring secondary to transplacental passage of maternal antibodies.[21,60,138]

In vitro bioassays assess the capacity of immunoglobulins to stimulate functional activity of the thyroid gland, such as adenylate cyclase stimulation, cAMP formation, colloid mobilization, or iodothyronine release. Such antibodies are often referred to as *thyroid-stimulating immunoglobulins* (TSIs). Measuring the increase in cAMP concentration has been accomplished using human thyroid slices, frozen human thyroid cells in culture, or a cloned line of thyroid follicular cells (FRTL-5).[102,215] The last of these has greatly

facilitated TSI measurements, and assays for TSIs can be performed in 1 day. In this test, the cell line is grown to confluency and then deprived of TSH. The thyroid cells then become very sensitive to stimulation by immunoglobulin G preparations from patients with Graves' disease. These immunoglobulins mimic the effect of TSH, activating adenylate cyclase. Cyclic AMP is subsequently released into the surrounding medium and assayed. The effect of stimulation is expressed as a percentage of basal activity; the range in normal serum is 70% to 130%. TSIs are present in 95% of patients with untreated Graves' disease. In addition to being a highly sensitive and specific indicator of Graves' disease, TSI measurement is also used for following the course of therapy and predicting relapse and remission.[59,145] However, the marginal clinical value of this test in individual patients together with its relatively high cost suggests that TSI may not be the ideal measure for the diagnosis and management of Graves' hyperthyroidism.[60]

CHAPTER 53

Reproductive Related Disorders*

Shannon Haymond, Ph.D.,
and Ann M. Gronowski, Ph.D.

Reproductive endocrinology encompasses the hormones of the hypothalamic-pituitary-gonadal axis, and the adrenal glands (see Chapters 50 and 51). These hormones are crucial for proper reproductive function, and include gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), and a multitude of sex steroids. The sex steroids are synthesized by the ovaries, testes, and adrenal glands, and are responsible for the manifestation of primary and secondary sex characteristics. Steroids that feminize are classified as estrogens; those that masculinize are known as androgens. Discussed in this chapter are (1) male reproductive biology, (2) female reproductive biology, (3) infertility, and (4) analytical methodology.

MALE REPRODUCTIVE BIOLOGY

Anatomy

The male reproductive anatomy includes the penis, two testes, and a system of exocrine glands whose secretions form the seminal fluid. The exocrine glands consist of the two bulbourethral glands (Cowper's glands), two seminal vesicles, and the prostate. The bilateral ducts that connect this system and transport sperm and seminal fluid are the epididymis, the vas deferens, and the ejaculatory duct, which enters the urethra.

The function of the testes is to synthesize both sperm and androgens. The mature testis contains a structured network of tightly packed seminiferous tubules. The lumina of the seminiferous tubules are lined by maturing germ cells and Sertoli cells (Figure 53-1). Sertoli cells play a crucial role in sperm maturation and secrete *inhibin*, a glycoprotein that inhibits the pituitary secretion of FSH.[130] Surrounding the seminiferous tubules are the interstitial Leydig cells, which are responsible for the production of testicular androgens. Testosterone is essential for sperm maturation and the complex endocrine feedback mechanism between Sertoli cells, Leydig cells, maturing sperm, the anterior pituitary, and the hypothalamus (Figure 53-1).

Hypothalamic-Pituitary-Gonadal Axis

GnRH is a decapeptide that is synthesized in the hypothalamus and transported to the anterior pituitary gland, where it stimulates the release of both FSH and LH (see Figure 53-1; see also Chapter 50).

In adult men, GnRH and thus LH and FSH are secreted in pulsatile patterns. A circadian rhythm is present, with higher concentrations found in the early morning hours and lower concentrations in the late evening.[342] LH acts on Leydig cells to stimulate the conversion of cholesterol to pregnenolone and in turn the synthesis of testosterone. The exact role of FSH is not yet clear; however, it is known that FSH acts on Sertoli cells to stimulate gametogenesis and the synthesis and release of inhibin. Sex steroids and inhibin together provide negative feedback control of LH and FSH secretion, respectively (see Figure 53-1). LH secretion is inhibited by testosterone and its metabolites, estradiol and dihydrotestosterone (DHT).[330] FSH may be elevated in disorders in which Sertoli cell numbers (and hence inhibin concentrations) are reduced. Likewise, a reduction in the number of Leydig cells (and hence testosterone secretion) leads to an elevation of LH concentration.

*The authors gratefully acknowledge the original contribution of R. J. Whitley, A. W. Meikle, and N. B. Watts, on which portions of this chapter are based.

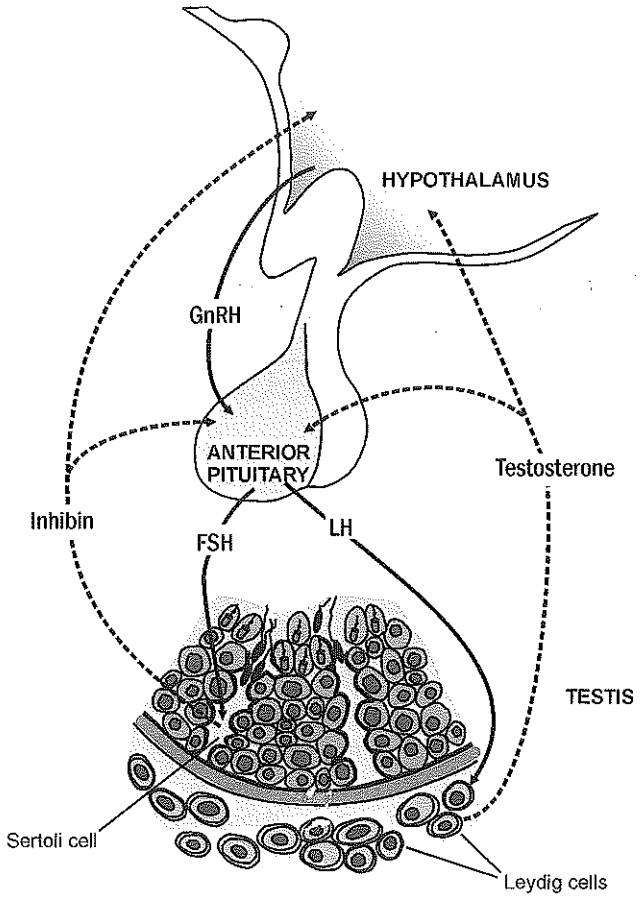

Figure 53-1 Summary of the endocrine control of the testis. *Dashed lines* indicate inhibitory effects, and *solid lines* stimulatory effects. *FSH,* Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone.

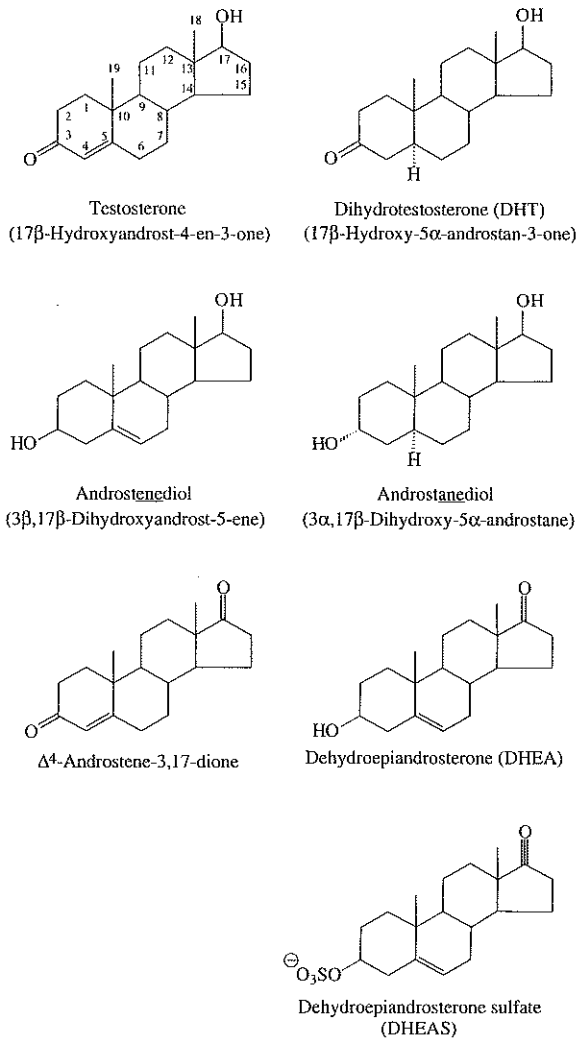

Figure 53-2 Chemical structure of androgens.

ANDROGENS

Function

Androgens are a group of C_{19} steroids (Figure 53-2) that cause masculinization of the genital tract and the development and maintenance of male secondary sex characteristics.[162,367] They also contribute to muscle bulk, bone mass, libido, and sexual performance in men. Testosterone is the main androgen secreted by the Leydig cells of the testes, and its production increases during puberty. Women produce about 5% to 10% as much testosterone as do men.

Testosterone directly affects some aspects of secondary sex development, such as deepening of the voice, increase of muscle mass, and libido. It also has indirect effects in tissue with high 5α-reductase activity, where it serves as a prehormone for formation of DHT (Figure 53-3). Other androgens secreted by the adrenal glands include dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEA-S), androstenedione, and androstenediol and by the gonads androstenedione and DHEA. These steroids can be metabolized to testosterone and DHT in target tissue.[162,367] The mean androgen production rates in men are testosterone, 7 mg/day; androstenedione, 1.4 mg/day; and DHT, 0.3 mg/day. In women androgen production rates are as follows: testosterone, 0.25 mg/day; androstenedione, 3.4 mg/day (cycling) and 1.6 mg/day (menopausal); DHT, 0.056 mg/day.[374]

Biochemistry and Physiology

Biosynthesis of Testosterone

The synthesis of androgens begins with the mobilization of cholesterol from depots of cholesterol esters stored in lipid droplets in the cytoplasm. The cholesterol in these droplets may be derived from lipoprotein cholesterol or de novo synthesis.[97,141] Cholesterol released from the lipid droplets migrates to the inner mitochondrial membrane, where pregnenolone formation occurs by the action of the cholesterol side-chain cleavage enzyme. The conversion of cholesterol to pregnenolone appears to be the rate-limiting step in testosterone synthesis.[130,318] The pathway for testosterone formation is shown in Figure 53-4, with the preferred pathway defined by heavy arrows.

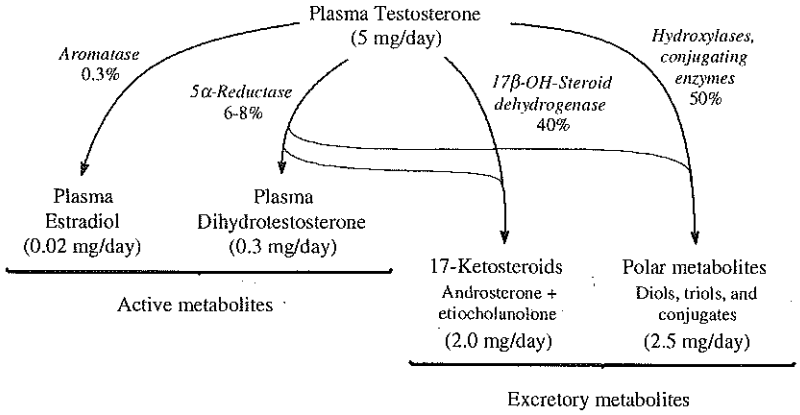

Figure 53-3 Pathways of peripheral metabolism of plasma testosterone. Testosterone can be metabolized either to active metabolites or to excretory metabolites. *(From Griffin JE, Wilson JD. The testis. In: Bondy PK, Rosenberg LE, eds. Metabolic control and disease. 8th ed. Philadelphia: WB Saunders Co, 1980:1535-78.)*

Androgen Transport in Blood

Testosterone and DHT circulate in plasma either free (approximately 2% to 3%) or bound to plasma proteins. The binding proteins include the specific sex hormone-binding globulin (SHBG) and nonspecific proteins such as albumin. SHBG is an α-globulin that has low capacity for steroids, but binds with very high affinity ($Ka = 1 \times 10^8$ to 1×10^9), whereas albumin has high capacity but low affinity ($Ka = 1 \times 10^4$ to 1×10^6).[248,255] SHBG has the highest affinity for DHT and lowest for estradiol. In men, testosterone circulates bound 44% to 65% to SHBG and 33% to 50% to albumin, whereas in women, testosterone is bound 66% to 78% to SHBG and 20% to 30% to albumin.[248,255]

For years, it was believed that the free fraction of testosterone represented the biologically active fraction. However, it is now thought that dissociation of protein-bound testosterone also occurs within a capillary bed. In studies of tissue delivery in vivo, nearly all of the albumin-bound testosterone was available for tissue uptake.[255] Therefore, the *bioavailable testosterone* is equal to about 35% of the total, or the free plus the albumin-bound.[130] The albumin-bound fraction is referred to as the "non–SHBG-bound" fraction or *weakly bound* fraction.

Testosterone and SHBG exhibit rhythmic variations in their circulating concentrations. Testosterone concentrations peak at approximately 0400 to 0800 hours and nadir concentrations occur at between 1600 and 2000 hours.[293,340] Daily variations in SHBG concentrations are similar to those of other proteins and albumin in serum, with major changes related to posture.[340] Concentrations of SHBG are elevated with hyperthyroidism and in hypogonadal men.[130]

Metabolism of Testosterone

Circulating testosterone serves as a precursor for the formation of two types of active metabolites (see Figure 53-3). Through the actions of 5α-reductase, 6%-8% of testosterone is converted to DHT. Alternatively, testosterone and androstenedione can be converted to estrogens (~0.3%) through aromatase.[130] DHT is formed in androgen target tissues, such as the skin and prostate, whereas aromatization occurs in many tissues. Peripheral aromatization occurs primarily in adipose tissue (of both men and women) because of the high concentration of aromatase in this tissue. The rate of extraglandular aromatization therefore increases with body fat.[130]

Dihydrotestosterone is metabolized to 3α-androstanediol (see Figure 53-4) and 3α-androstanediol glucuronide. These metabolites have been used as markers of DHT production in peripheral tissues. Serum concentrations of 3α-androstanediol glucuronide or 3α-androstanediol reflect the production of DHT in peripheral tissue such as skin.[154,206] However, DHT may also arise from precursors other than testosterone. The reduction in serum 3α-androstanediol glucuronide concentrations in patients treated with glucocorticoids that suppress adrenal glucocorticoid and androgen production supports this conclusion.[223]

The main excretory metabolites of androstenedione, testosterone, and DHEA are shown in Figure 53-5. Except for epitestosterone, these catabolites constitute a group of steroids known as *17-ketosteroids* (17-KSs). These metabolites are excreted primarily in the urine (>90%), with approximately half as 17-KSs, and half as diols, triols, conjugates, and other polar compounds.[130]

Male Reproductive Development

Fetal

During early embryogenesis, the fetus possesses the genital ducts for both the female and male reproductive tracts—mullerian and wolffian ducts, respectively. The mullerian ducts have the potential to differentiate into the fallopian tubes, uterus, and upper part of the vagina of the female reproductive tract. The wolffian ducts differentiate into the vas deferens, epididymis, and seminal vesicles of the male reproductive tract. In male fetuses, testosterone is responsible for maintaining the wolffian ducts and for virilization of the urogenital sinus and external genitalia. Mullerian inhibiting substance (MIS) is responsible for the regression of the mullerian ducts.[130] MIS is the earliest known secretory product of the Sertoli cells in the fetal testis. Mutations in the gene for MIS, or its receptor, are responsible for the lack

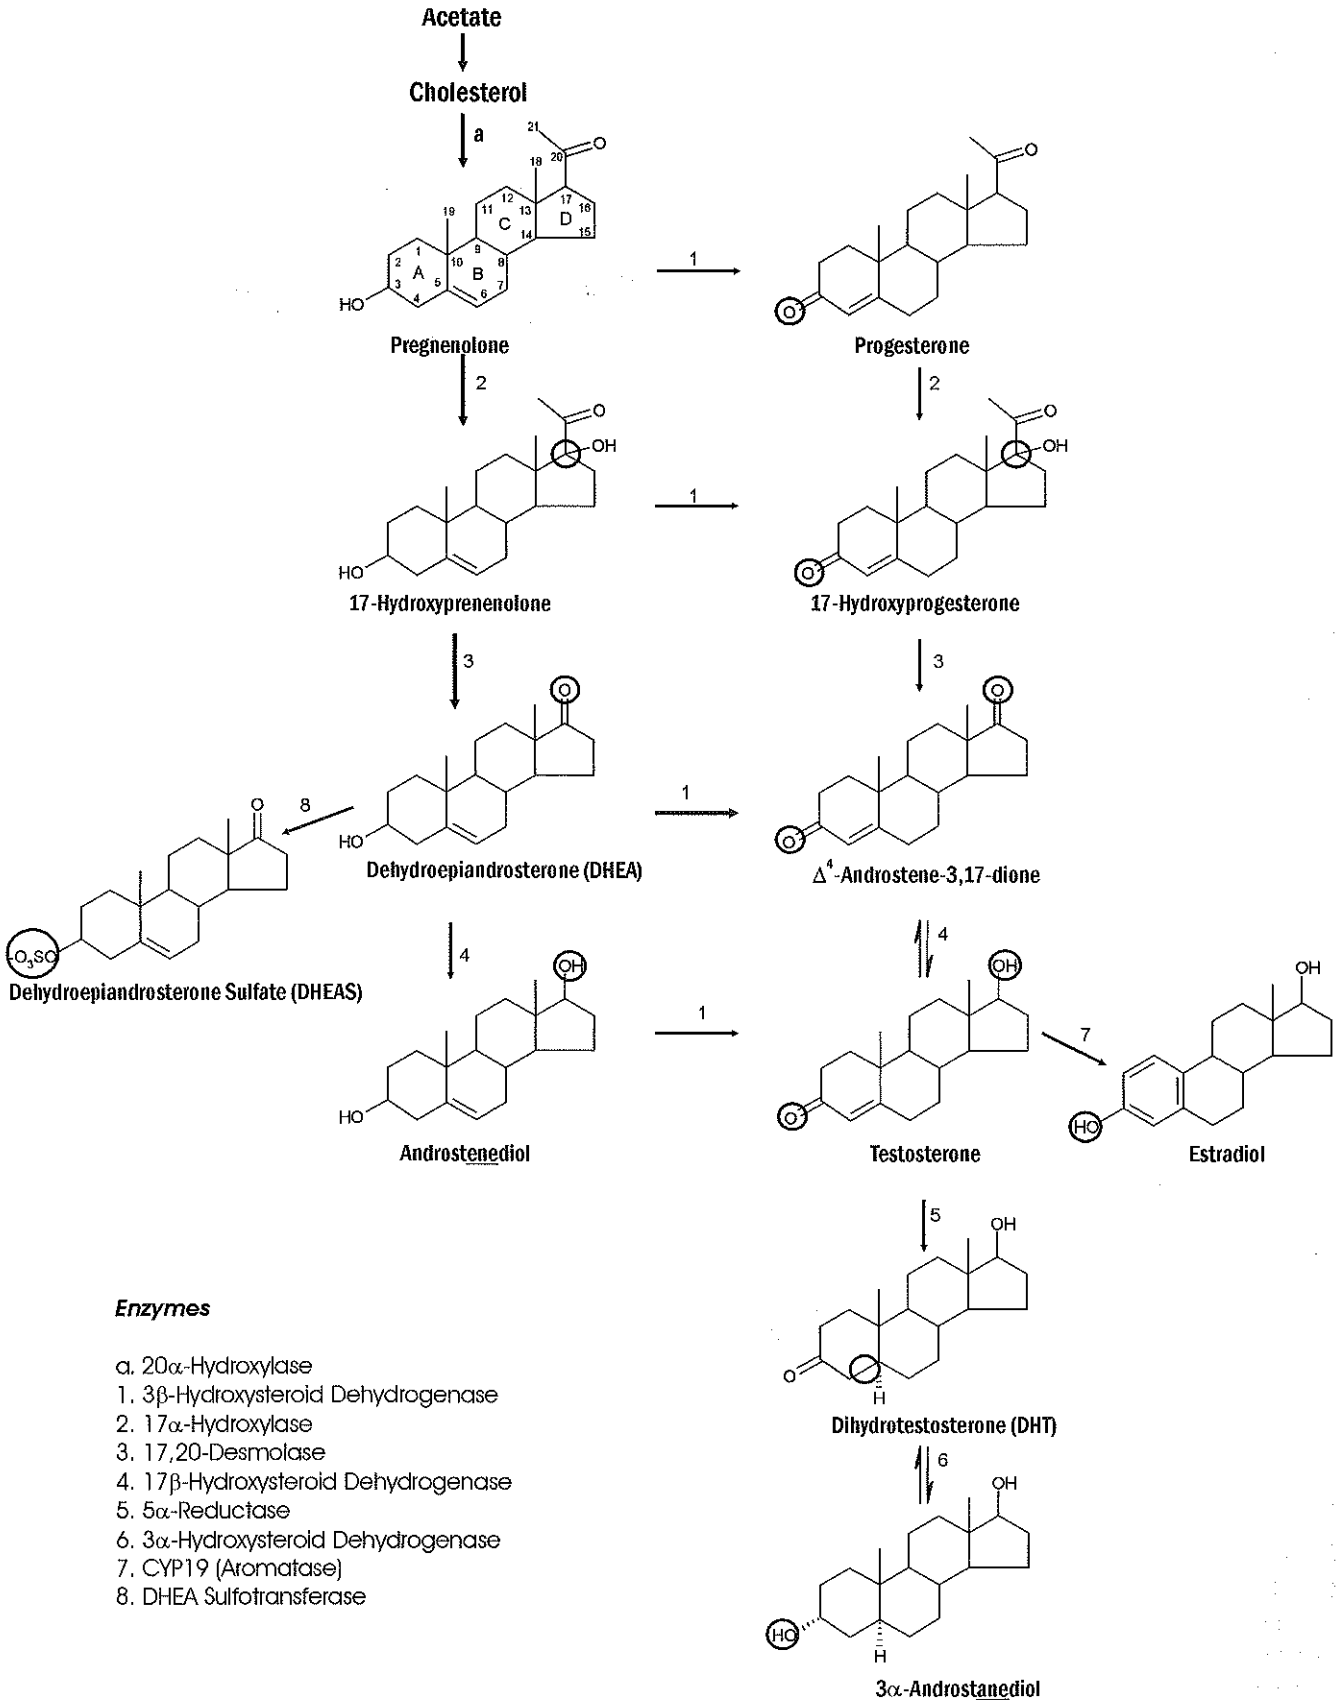

Figure 53-4 Biosynthesis of androgens (adrenal glands and testis). The *heavy arrows* indicate the preferred pathway. The *enclosed area* represents the site of chemical change.

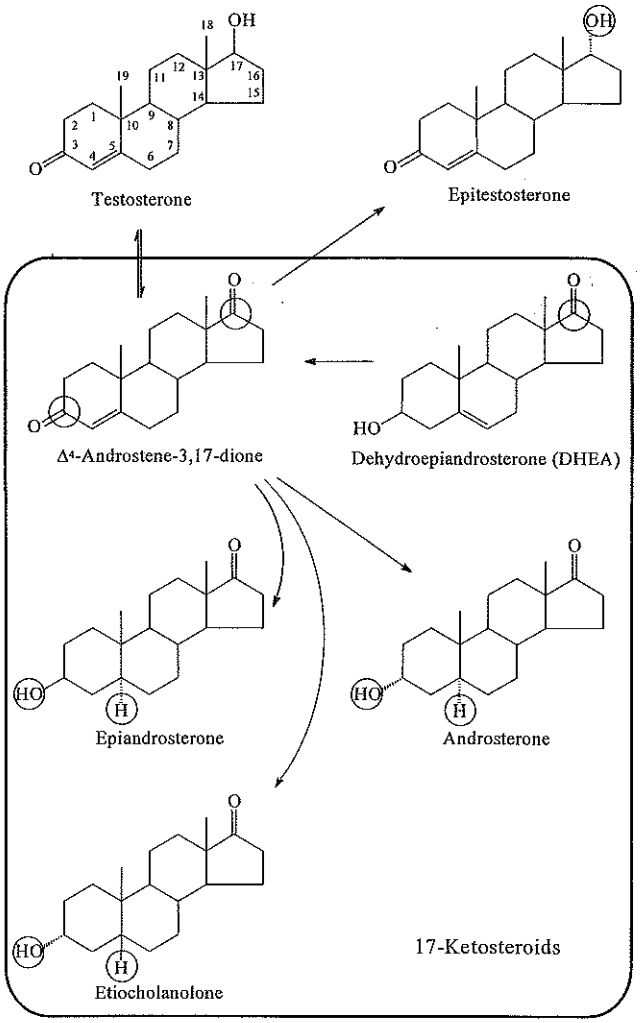

Figure 53-5 Catabolism of $C_{19}O_2$ androgens. The *circled area* represents the site of chemical change.

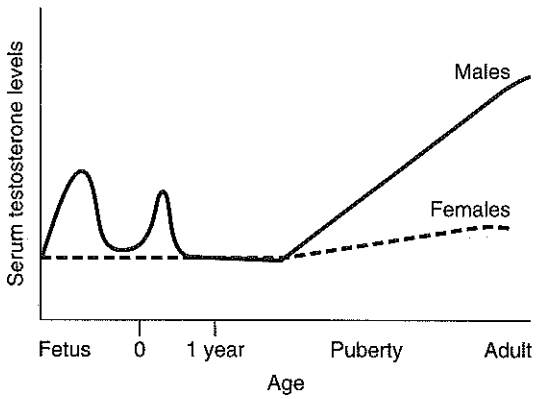

Figure 53-6 Schematic drawing of the changes in male and female total serum testosterone throughout life. *(From Wheeler MJ. The determination of bio-available testosterone. Ann Clin Biochem 1995;32:353-7.)*

of regression of the mullerian ducts in patients with persistent mullerian duct syndrome.[114] For normal male sexual development to occur, there must be production of MIS and testosterone, conversion of testosterone to DHT, and functioning androgen receptors.[162,367] A microphallus (<2.5 cm fully stretched length) at birth can be caused by lack of testosterone or DHT, or defective androgen receptors. In the male embryo, the production of testosterone by the testes, and the concentration of plasma testosterone, start to rise by the second month of gestation and peak at 12 weeks at approximately 5.5 nmol/L.[357] A high concentration is maintained until it decreases late in gestation (see Figure 53-6).[357,367]

Several enzyme defects will cause a deficiency of testosterone production during fetal development. These include *20α-hydroxylase (cholesterol 20,22-desmolase) deficiency*, which prevents conversion of cholesterol to pregnenolone and results in congenital lipoid adrenal hyperplasia, so named because the adrenals are large and filled with lipoid material.[189] Affected male fetuses have female or ambiguous genitalia. Urinary 17-KSs are completely absent.[167,189] This disorder causes severe salt wasting and can be fatal if not treated early.

When the condition of *17α-hydroxylase deficiency* occurs, the production of cortisol and sex steroids (except for progesterone) is impaired and the production of mineralocorticoids increased (see Figure 51-4, Chapter 51).[189] With this deficiency, plasma concentrations of corticosterone, 11-deoxycorticosterone, progesterone, and pregnenolone are elevated. Boys exhibit pseudohermaphroditism and deficiency in development of secondary sex characteristics.

Boys with *17β-hydroxysteroid dehydrogenase deficiency* fail to form testosterone from androstenedione, androstenediol from DHEA, or estradiol from estrone in a normal manner (see Figure 53-4). At puberty, plasma concentrations of testosterone and DHT are low, and plasma androstenedione and estrone are elevated in those individuals.[312]

Postnatal

At birth, the concentration of testosterone is only slightly higher in boys than in girls. Shortly after birth, the concentration of testosterone increases, remains elevated for about 3 months, and then falls to baseline again by 1 year (<1 nmol/L). The concentration of androgens remains low, although higher in boys than in girls, until puberty (see Figure 53-6).[130]

Puberty

Concentrations of androstenedione, DHEA, and DHEA-S begin to increase as early as 6 to 7 years of age, several years before maturation of the hypothalamic-pituitary-gonadal axis. The onset of puberty is associated with nocturnal surges in LH and, to a lesser extent, FSH secretion. The overall changes associated with puberty reflect the theory that the hypothalamic-pituitary system becomes less sensitive to feedback inhibition by circulating androgens, resulting in

higher androgen concentrations. Androgen secretion during puberty appears to be necessary for normal bone density and is associated with a fall in high-density lipoprotein concentrations, and an increase in hematocrit. On average, puberty is completed between the ages of 16 and 19.[130]

Andropause

Increased life expectancy has generated interest in aging-related health problems and among those is the gradual decrease in gonadal function in men after the age of 50. The aging process in men leads to the physiological lowering of androgens including testosterone. Because it parallels the changes observed in the aging female during menopause, this state has been referred to as andropause.[230,319,328] The clinical presentation of andropause is symptomatic or asymptomatic, with symptoms including decreased well-being, energy levels, and sexual function. Unlike its female counterpart, andropause does not result in universal or absolute loss of gonadal function and the process is much more gradual, progressing over several decades. Thus alternate names such as androgen decline in the aging male (ADAM) or partial androgen deficiency in the aging male (PADAM) have been suggested to describe this biochemical and physiological state.[229]

Age-related decreases in testicular androgen production are primarily caused by a decline in the number of Leydig cells.[143,238,355] Both total and free testosterone concentrations decrease with age on average 3.2 ng/dL (0.11 nmol/L) per year.[143] The mean testosterone concentration at 80 years old is approximately 60% of that at 20 to 50 years.[344] Testosterone concentrations are affected by a number of factors—namely, age, obesity, time of day, and binding protein concentrations (albumin and SHBG). Free (or bioavailable) testosterone measurements of morning specimens are considered the most accurate indicator of androgenicity and are therefore the preferred laboratory test in the diagnosis of andropause.[346] Androgen replacement therapy is available as a form of treatment when indicated by severity of symptoms along with low circulating concentrations of bioavailable testosterone (typically <4 nmol/L).[78,230,319,328] There is considerable uncertainty regarding the long-term effects of androgen replacement therapy on the prostate. Specifically, the role of exogenous testosterone in the pathogenesis of benign prostatic hyperplasia and prostate cancer has not been determined.

Male Reproductive Abnormalities

There are a number of abnormalities that can affect the male reproductive system before birth, in childhood, or in adulthood. For the purposes of this chapter, they have been divided into categories of (1) hypogonadotropic hypogonadism, (2) hypergonadotropic hypogonadism, (3) defects in androgen action (Box 53-1), (4) impotence, and (5) gynecomastia. The effects of these abnormalities on infertility are discussed later in this chapter.

BOX 53-1 Male Reproductive Abnormalities

Hypogonadotropic Hypogonadism
- Panhypopituitarism (congenital or acquired)
- Hypothalamic syndrome (acquired or congenital)
  - Structural defects (neoplastic, inflammatory, and infiltrative)
  - Prader-Willi syndrome
  - Laurence-Moon-Biedl syndrome
- GnRH deficiency (Kallmann's syndrome)
- Hyperprolactinemia (prolactinoma or drugs)
- Malnutrition and anorexia nervosa
- Drug-induced suppression of luteinizing hormone (androgens, estrogens, tranquilizers, antidepressants, antihypertensives, barbiturates, cimetidine, GnRH analogs, and opiates)

Hypergonadotropic Hypogonadism
- Acquired (irradiation, mumps orchitis, castration, and cytotoxic drugs)
- Chromosome defects
  - Klinefelter's syndrome (47, XXY) and mosaics
  - Autosomal and sex chromosomes, polyploidies
  - True hermaphroditism
- Defective androgen biosynthesis
  - 20α-Hydroxylase (cholesterol 20,22-desmolase) deficiency
  - 17,20-Lyase deficiency
  - 3β-Hydroxysteroid dehydrogenase deficiency
  - 17α-Hydroxylase deficiency
  - 17β-Hydroxysteroid dehydrogenase deficiency
- Testicular agenesis
- Selective seminiferous tubular disease
- Miscellaneous
  - Noonan's syndrome (short stature, pulmonary valve stenosis, hypertelorism, and ptosis)
  - Streak gonads
  - Myotonia dystrophica
  - Acute and chronic diseases

Defects in Androgen Action
- Complete androgen insensitivity (*testicular feminization*)
- Incomplete androgen sensitivity
  - Androgen receptor defects
  - 5α-Reductase deficiency

GnRH, Gonadotropin-releasing hormone.

Hypogonadotropic Hypogonadism

Male hypogonadism is a condition caused by a decreased function of the testes that can lead to retardation of sexual development if manifested early in life. The disorder can be classified as *hypo*gonadotropic or *hyper*gonadotropic.

Hypogonadotropic hypogonadism occurs when defects in the hypothalamus or pituitary prevent normal gonadal stimulation. Causative factors include congenital or acquired panhypopituitarism, hypothalamic syndromes, GnRH deficiency, hyperprolactinemia, malnutrition or anorexia, and

iatrogenic causes. These abnormalities are all associated with decreased testosterone and gonadotropin concentrations.

Kallmann's syndrome is the most common form of hypogonadotropic hypogonadism and results from a deficiency of GnRH in the hypothalamus during embryonic development.[136] It is characterized by hypogonadism and anosmia (loss of the sense of smell) in male or female patients, and is inherited as an autosomal dominant trait with variable penetrance.[46,293] This syndrome arises from a defect in the migration of GnRH neurons to the hypothalamus. The pituitary disorders may be characterized by isolated gonadotropin deficiency or may be combined with growth hormone deficiency. Patients with the isolated disorder display sexual infantilism and long arms and legs; those with the combined deficiency do not have long arms and legs. These patients must be distinguished from those with growth delay. In all of these patients, LH, FSH, and testosterone concentrations are lower than normal. However, heterogeneity exists in the degree of gonadotropin deficiency, and hence urinary concentrations of LH, FSH, and testosterone have been shown to vary between affected patients (FSH: 10 to 500 mIU/hr; LH: 10 to 700 mIU/hr; testosterone: 5 to 60 ng/dL).[293]

Hypergonadotropic Hypogonadism

Hypergonadotropic hypogonadism arises from a primary gonadal disorder. Patients with primary testicular failure have elevated concentrations of LH and FSH and decreased concentrations of testosterone. Causes for primary hypogonadism include testicular damage such as from irradiation, disease, or drugs; chromosomal defects; enzymatic defects in androgen synthesis; testicular agenesis; and seminiferous tubular disease, among other miscellaneous causes. Aging is also associated with gonadal failure, which occurs in about 20% of men older than 60 years of age who exhibit defects both in primary Leydig cell function and in abnormal secretion of gonadotropins in response to GnRH (see earlier section on andropause).[34,293,330]

Defects in Androgen Action

The most common and severe defect in androgen action is *testicular feminization syndrome.* These individuals have female habitus and develop breast tissue; however, the vagina ends in a blind pouch and male testes are present. This disorder is thought to arise from a defect in the androgen receptor. Circulating concentrations of testosterone in these patients are the same as or greater than in normal men.[167] Testosterone can serve as a substrate for further estrogen formation, which may account for the elevated estrogen concentrations in these individuals.[167] Concentrations of LH are also increased, presumably because of the resistance of the hypothalamic-pituitary system to androgen inhibition.

Males with *5α-reductase deficiency* also have ambiguous genitalia.[367] If the deficiency remains undiagnosed before puberty, patients have an increase in muscle mass, voice change, and enlargement of the phallus; however, they lack normal male-pattern hair growth, and their prostate gland remains small. There is evidence that DHT formation is deficient in the tissue of the urogenital tract in these patients.[167]

In patients with cryptorchidism or ambiguous genitalia, the identification of abdominal gonads is essential for proper diagnosis and treatment. Measurement of plasma MIS has been advocated for detecting the presence of testicular tissue.[114,194,228] However, this test is not yet commercially available. The best indication for the use of MIS measurement is as a first approach to the differentiation between cryptorchidism and anorchidism in boys with a normal phenotype but undescended testes. Mean plasma MIS concentration in anorchid patients was 0.8 ng/mL, compared with 48.2 ng/mL in patients with normal testes.[194] MIS concentrations are also elevated in boys with delayed puberty and partial androgen insensitivity. Other reports suggest that inhibin B may be used as a basal serum marker for the presence and function of testicular tissue in boys with nonpalpable testicles.[4,134,186] Kubini and co-workers found that boys with anorchia have undetectable serum inhibin B concentrations.[186] Boys with severe testicular damage or gonadal dysgenesis also have undetectable or very low concentrations of inhibin B, whereas normal serum inhibin B concentrations are observed for boys with abdominal "normal" testes.[186]

Impotence

Impotence is the persistent inability to develop or maintain a penile erection that is sufficient for intercourse and ejaculation in 50% or more of attempts.[185,293] A wide variety of organic and psychological abnormalities may cause changes in sexual drive and the ability to have an erection or to ejaculate. Psychogenic impotence is the most common diagnosis. Other causes include vascular disease, diabetes mellitus, hypertension, uremia, neurologic disease, hypogonadism, hyperthyroidism and hypothyroidism, neoplasms, and drugs. The physician must pursue a careful evaluation of the possible psychological factors, neuropathy, or vascular abnormalities that may be interfering with proper sexual function. If no obvious explanation for impotence can be found, measurements of morning serum testosterone, LH, and thyroid-stimulating hormone concentrations have been suggested.[128,293] Elevated gonadotropin concentrations indicate primary hypogonadism. Total and even free testosterone concentrations may be within normal reference intervals, yet still may be subnormal for a given patient if found in the presence of elevated LH or FSH. Hyperprolactinemia is an infrequent cause of impotence but should be considered in unusual situations.

Sildenafil (Viagra) was approved by the FDA in April 1998 for use as an oral therapeutic agent for male erectile dysfunction.[25,26,147,233,296] It has been found to be a selective inhibitor of phosphodiesterase 5 (PDE5).[26] A high-

performance liquid chromatography (HPLC) method for sildenafil has been reported.[65] Cialis and Levitra are other PDE5 inhibitors that are used to treat male erectile dysfunction (http://www.erectile-dysfunction-impotence.org/).

Gynecomastia

Gynecomastia is the benign growth of glandular breast tissue in men and is a common finding in males of varied ages.[33,120,217] Gynecomastia is associated with an increase in the estrogen/androgen ratio. There are three distinct periods of life with which gynecomastia is commonly associated. First, transient gynecomastia can be found in 60% to 90% of all newborns because of high estrogen concentrations that cross the placenta. The second peak occurs during puberty in 50% to 70% of normal boys. It is usually self-limited and may be caused by low serum testosterone, low DHT, or a high estrogen/androgen ratio. The last peak is found in the adult population, most frequently 50- to 80-year-old men. This gynecomastia may be due to testicular failure, resulting in an increased estrogen/androgen ratio, or to increased body fat, resulting in increased peripheral aromatization of testosterone to estradiol.[33,120,217]

Gynecomastia may also develop because of iatrogenic causes[334] or hyperthyroidism.[120] Finally, germinal cell or nonendocrine tumors that produce human chorionic gonadotropin (hCG), and estrogen-producing tumors of the adrenal glands, the testes, or the liver can cause gynecomastia. hCG can stimulate testicular aromatase activity and estrogen production.[120] In cases of striking gynecomastia in which history and physical examination point to no specific disorder, measurements of hCG, plasma estradiol, testosterone, and LH concentrations are appropriate.[33] It is important to note that prolactin plays an important role in *galactorrhea* (milk production), but only an indirect role in gynecomastia.

FEMALE REPRODUCTIVE BIOLOGY

Anatomy

The female reproductive system consists of a vagina, a uterus, and the bilateral fallopian tubes and ovaries. The ovaries are located on either side of the uterus in close proximity to the fallopian tubes. They function as both the producers of ova and the secretors of the sex hormones progesterone and estrogens.

Every healthy female neonate possesses approximately 400,000 primordial follicles, each containing an immature ovum. During the reproductive life span of an adult woman, 300 to 400 follicles will reach maturity.[112,127] A single mature follicle is produced during each normal menstrual cycle at approximately day 14 (Figure 53-7). Surrounding the oocyte of the mature follicle are three distinct cell layers: the *theca externa*, the *theca interna*, and the *granulosa cells*. The theca interna cells are the primary source of androgens, which are transported to adjacent granulosa cells, where they are aromatized to estrogens.[46]

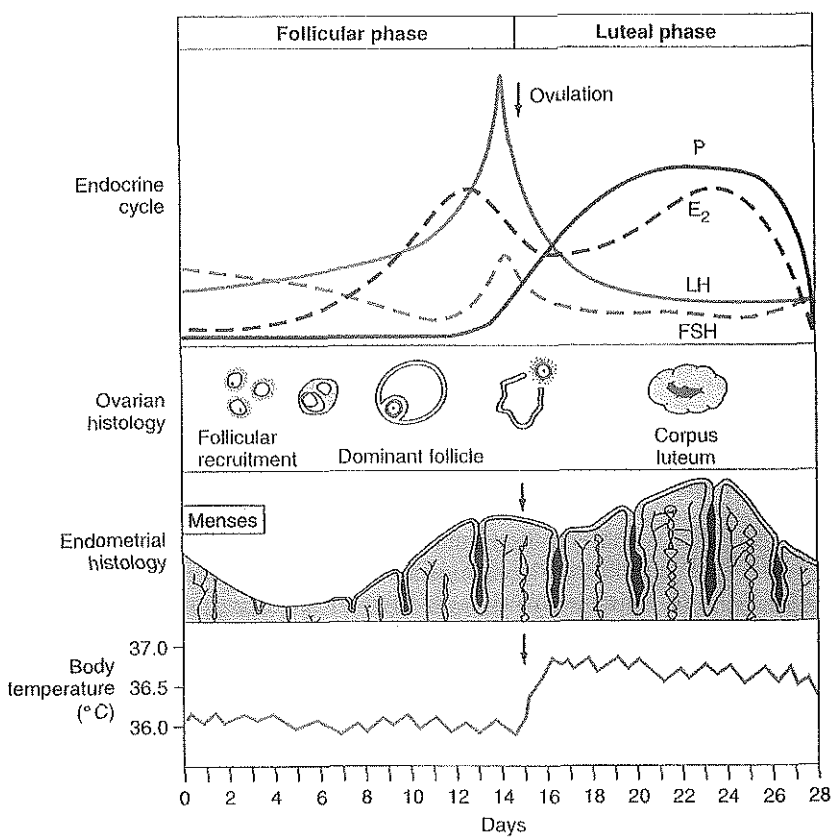

Figure 53-7 The hormonal, ovarian, endometrial, and basal body temperature changes throughout the normal menstrual cycle. *(From Carr BR, Bradshaw KD. Disorders of the ovary and female reproductive tract. In Braunwald E, Fauci A, Kasper D, Hauser SL, Longo DL, Jameson JL, eds. Harrison's principles of internal medicine. 15th ed. New York: McGraw-Hill Co, 2001:2158.)*

The mature follicle undergoes ovulation by the process of rupture, thereby releasing the oocyte into the proximity of the fallopian tubes. The follicle then fills with blood to form the corpus hemorrhagicum. The granulosa and theca cells of the follicle lining quickly proliferate to form lipid-rich luteal cells, replacing the clotted blood and forming the *corpus luteum* (yellow body). The luteal cells produce estrogen and progesterone. If fertilization and pregnancy occur, the corpus luteum persists and continues to produce estrogen and progesterone. If no pregnancy occurs, the corpus luteum regresses and is eventually replaced by scar tissue.

The fallopian tubes arise from the uterus and extend toward the ovaries. They convey the sperm upward from the uterine cavity and provide the site for fertilization of the oocyte. The fertilized egg is transported back along the fallopian tubes to the uterine cavity. The uterine cavity is lined by the endometrium. The endometrium undergoes cyclical changes in preparation for implantation and pregnancy. During the luteal phase, the endometrial lining increases in thickness and vascularity; during menstruation, the endometrium is shed (Figure 53-7).

Hypothalamic-Pituitary-Gonadal Axis

In adult women, a tightly coordinated feedback system exists between the hypothalamus, anterior pituitary, and ovaries to orchestrate menstruation. FSH serves to stimulate follicular growth and LH stimulates ovulation and progesterone secretion from the developing corpus luteum (see Figure 53-8). These actions are discussed in greater depth later in this chapter.

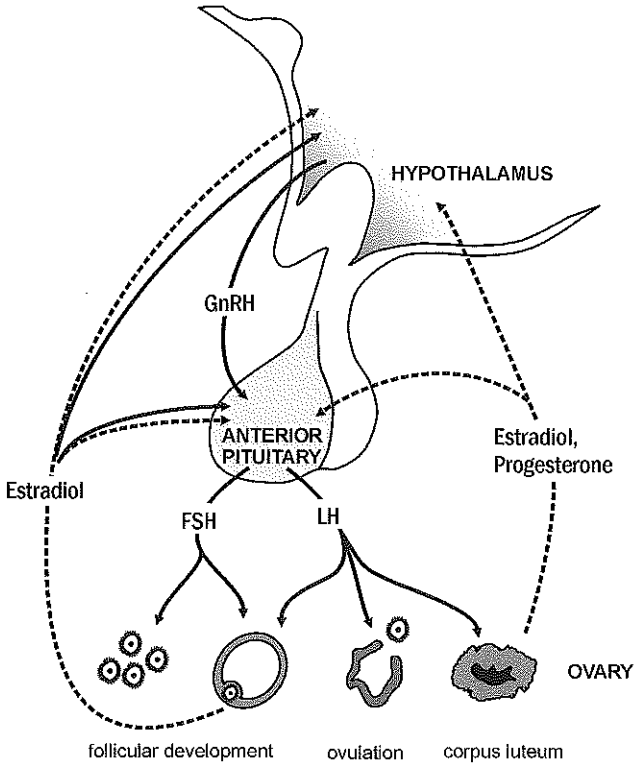

Figure 53-8 Summary of the endocrine control and changes in ovary and endometrium during the menstrual cycle. *Dashed lines* indicate inhibitory effects, and *solid lines* stimulatory effects. *FSH,* Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone.

Estrogens

Function

Estrogens are sex hormones that are responsible for the development and maintenance of the female sex organs and female secondary sex characteristics. In conjunction with progesterone, they also participate in the regulation of the menstrual cycle and breast and uterine growth, and in the maintenance of pregnancy.

Estrogens affect calcium homeostasis and have a beneficial effect on bone mass. They decrease bone resorption, and in prepubertal girls estrogen accelerates linear bone growth and results in epiphyseal closure.[130] Long-term estrogen depletion is associated with loss of bone mineral content, an increase in stress fractures, and postmenopausal osteoporosis.[180]

Estrogens also have well established effects on plasma proteins that influence endocrine testing. They increase concentrations of SHBG, corticosteroid-binding globulin, and thyroxine-binding globulin.[255,356] Hence, boys and girls have comparable concentrations of SHBG, but adult men have SHBG concentrations that are about one half those of adult women. Concentrations of plasma proteins that bind copper and iron are also elevated in response to estrogen, as are those of high-density and very high-density lipoproteins. The rise in very high-density lipoprotein concentrations and the increase in lipogenesis in the liver may cause triglyceride elevation. In addition, estrogens are believed to play a preventive role in coronary heart disease.[131]

Chemistry

The names and structural formulas of some of the important estrogens are shown in Figure 53-9. Structurally, estrogens are derivatives of the parent hydrocarbon *estrane,* which is an 18-carbon molecule with an aromatic ring A and a methyl group at C-13.[46,373] Estrogens possess a phenolic hydroxyl group at C-3, which gives the compounds acidic properties, do not possess a methyl group at C-10 (as do androgens), and may possess a ketone (estrone) or hydroxyl group (estradiol) at C-17 and frequently at C-16 (estriol). The phenolic ring A and the oxygen function at C-17 are essential for biological activity. Substituents at other positions in the molecule diminish feminizing potency. For example, estriol that contains a hydroxyl group at C-16 possesses very little biological activity.

Biochemistry and Physiology

Estrogen Biosynthesis

In normal women, most estrogens are secreted by the ovarian follicles and the corpus luteum, and during pregnancy by the placenta. Adrenals and testes are also believed

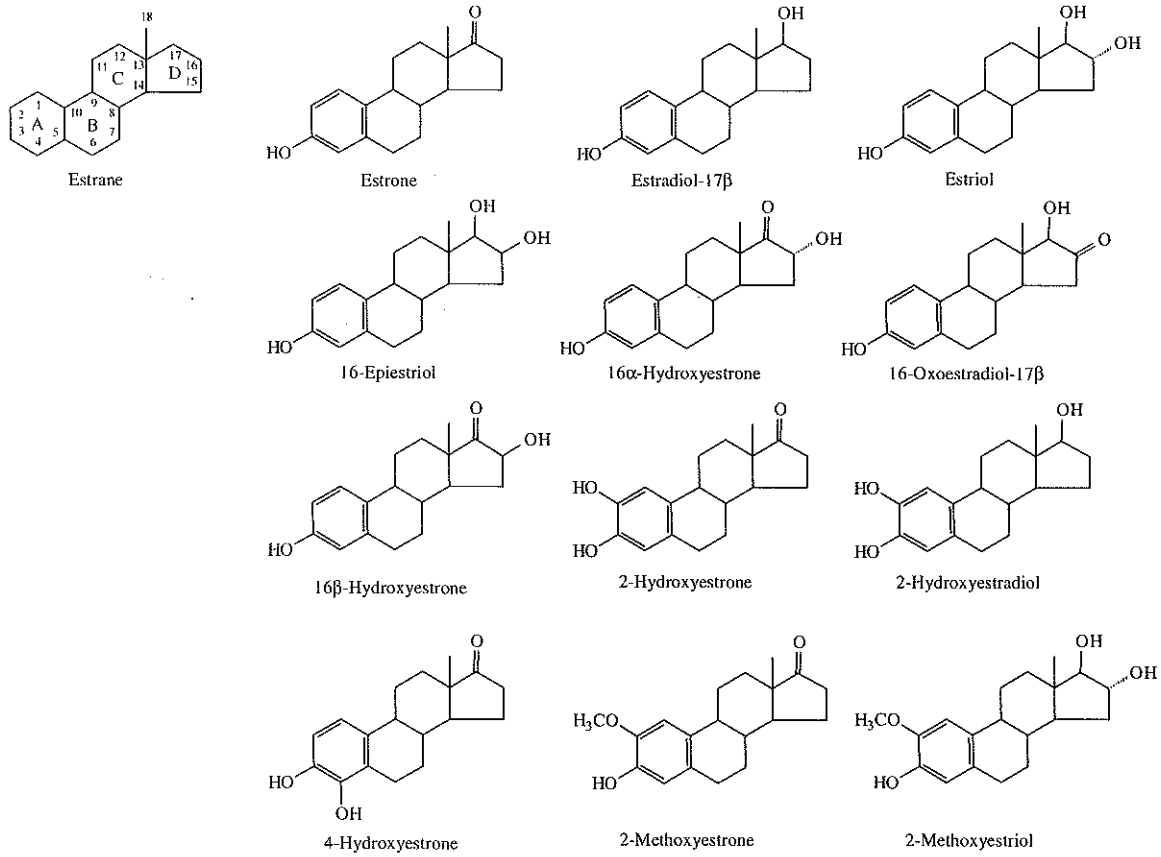

Figure 53-9 Structural formulas of important estrogens.

to secrete minute quantities of estrogens. The ovary follows the same steroidogenic pathway as do the other steroid-producing organs.[46,373] In vivo and in vitro studies indicate that acetate, cholesterol, progesterone, and testosterone can all serve as precursors of estrogens. The normal human ovary produces all three classes of sex steroids—estrogens, progestins, and androgens; however, estradiol and progesterone are its primary secretory products. Unlike the testis, the ovary possesses a highly active aromatase system that rapidly converts androgens such as testosterone to estrogens. Unlike the adrenal cortex, the normal ovary lacks both the 21-hydroxylase and the 11β-hydroxylase enzymes, and therefore cannot produce glucocorticoids and mineralocorticoids.[46,373] More than 20 estrogens have been identified, but only 17β-estradiol (also denoted as *E2*) and estriol (also denoted as *E3*) are routinely measured clinically. The most potent estrogen secreted by the ovary is 17β-estradiol. Because it is derived almost exclusively from the ovaries, its measurement is often considered sufficient to evaluate ovarian function.

The biochemical pathway illustrating the aromatization of testosterone to estradiol and androstenedione to estrone is shown in Figure 53-10. Steroidogenesis and its regulation during the menstrual cycle have been discussed in detail by Channing and associates.[54] The role of estrogens in normal and abnormal menstrual cycles is described later in this chapter.

Estrogens are also produced by peripheral aromatization of androgens, primarily androstenedione. In healthy men and women, ~1% of the secreted androstenedione is converted to estrone.[46,373] Although the ovaries of postmenopausal women do not secrete estrogens, these women have significant blood concentrations of estrone originating from the peripheral conversion of adrenal androstenedione. Because a major site of this conversion is adipose tissue, estrone increases in obese postmenopausal women, sometimes yielding enough estrogen to produce bleeding.[46,373,376] The significance of extraglandular estrogen production in health and disease has been discussed at length by Siiteri and MacDonald.[305]

Biosynthesis of Estriol During Pregnancy

Research has shown that biosynthesis of estrogens differs qualitatively and quantitatively in pregnant women compared with nonpregnant ones. In pregnant women, the major source of estrogens is the placenta, whereas in nonpregnant women, the ovaries are the main site of synthesis.[46,373,376] In contrast to the microgram quantities secreted

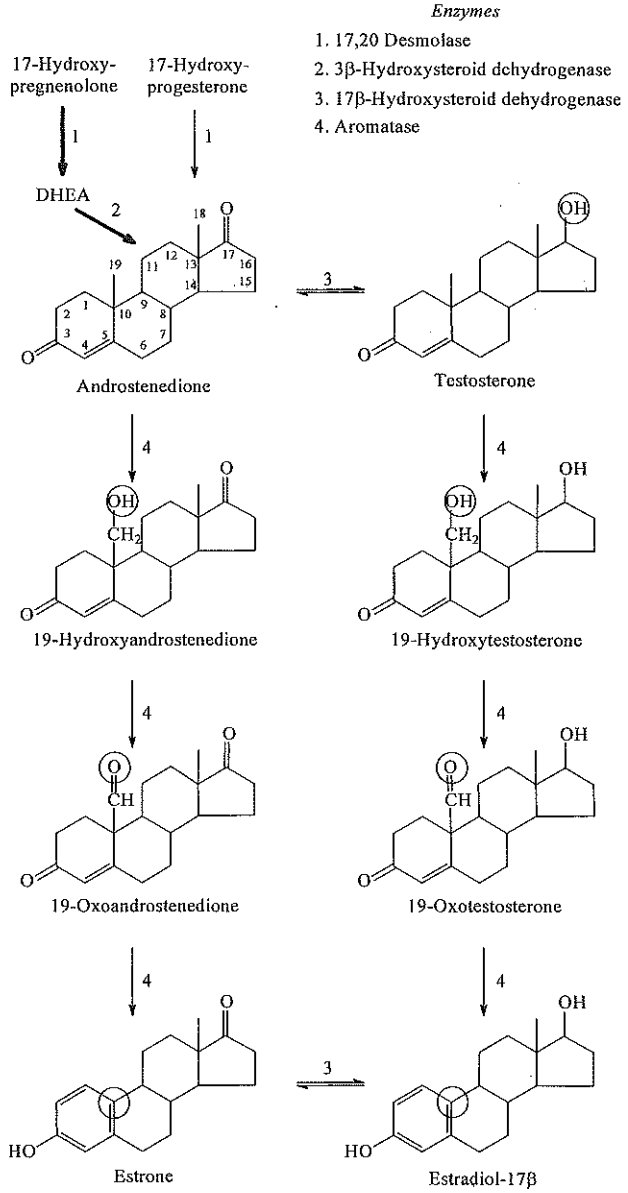

Figure 53-10 Biosynthesis of estrogens. *Heavy arrows* indicate the Δ5-3β-hydroxy pathway. The *circled area* represents the site of chemical change. See Figure 53-5 for the early synthetic steps.

by nonpregnant women, the amount of estrogen secreted during pregnancy increases to milligram amounts. The major estrogen secreted by the ovary is estradiol, whereas the major product secreted by the placenta is estriol. Estriol is formed in the placenta by sequential desulfurylation and aromatization of plasma DHEA-S. Except during pregnancy, measurements of estriol have little clinical value, because in nonpregnant women estriol is derived almost exclusively from estradiol (see also Chapter 54).

Estriol is the predominant hormone of late pregnancy. Maternal estriol is almost entirely (~90%) derived from fetal and placental sources. It is first detected during the 9th gestational week and gradually increases during the first and second trimesters. Plasma and salivary estriol concentrations peak approximately 3 to 5 weeks before labor and delivery.[125] This characteristic surge in estriol has been observed for term, preterm, and postterm pregnancies. Some reports have suggested utility in the measurement of salivary estriol in the prediction of risk for spontaneous preterm birth.[124,148-150,187,219] This test has a high negative predictive value but low positive predictive value. Currently, the American College of Obstetrics and Gynecologists does not suggest measuring salivary estriol concentrations except for research purposes.[2] Details regarding the techniques used to determine serum and salivary estriol concentrations are discussed in the section on analytical methods.

Serum estriol measurements are commonly used as part of the "triple" or "quad" maternal screens for Down syndrome–affected fetuses (see Chapter 54). On average, unconjugated estriol is 0.72 times less than normal (median value at 16 weeks: 0.30 to 1.50 μg/L) when fetal Down syndrome is present.[43,222,329,349]

Estrogen Transport in Blood

Greater than 97% of circulating estradiol is bound to plasma proteins. It is bound specifically and with high affinity to SHBG and nonspecifically to albumin.[248,318] SHBG concentrations are increased by estrogens and therefore are higher in women than in men. They are also increased during pregnancy, oral contraceptive use, hyperthyroidism, and administration of certain antiepileptic drugs, such as Dilantin. SHBG concentrations may decrease in hypothyroidism, obesity, or androgen excess. In women, estradiol circulates bound 40% to 60% to SHBG and 40% to 60% to albumin. SHBG has a higher affinity for testosterone than estradiol; therefore in men, estradiol circulates 20% to 30% bound to SHBG and 70% to 80% bound to albumin.[248,255] Only 2% to 3% of total estradiol circulates in the free form. In contrast, estrone and estrone sulfate circulate bound almost exclusively to albumin. As with testosterone, both the free and albumin-bound fractions of estradiol are thought to be biologically available,[255] but measurement of this fraction has not been shown to be clinically important.

In the normal, nonpregnant woman, estradiol is produced at the rate of 100 to 300 μg/day.[46,305,373] The production of estrone ranges from 100 to 200 μg/day. Diurnal variation of blood estrone concentrations occurs in postmenopausal women, presumably reflecting the variation in the androstenedione precursor that originates in the adrenal glands. However, no such diurnal rhythms have been demonstrated for estradiol.

Metabolism of Estrogens

In the normal course of estrogen metabolism (Figure 53-11), estradiol is believed to form a reversible redox system with estrone. Normally, blood estrone concentrations parallel estradiol concentrations throughout the menstrual cycle, but at one third to one half their magnitude.[261] Estrone is

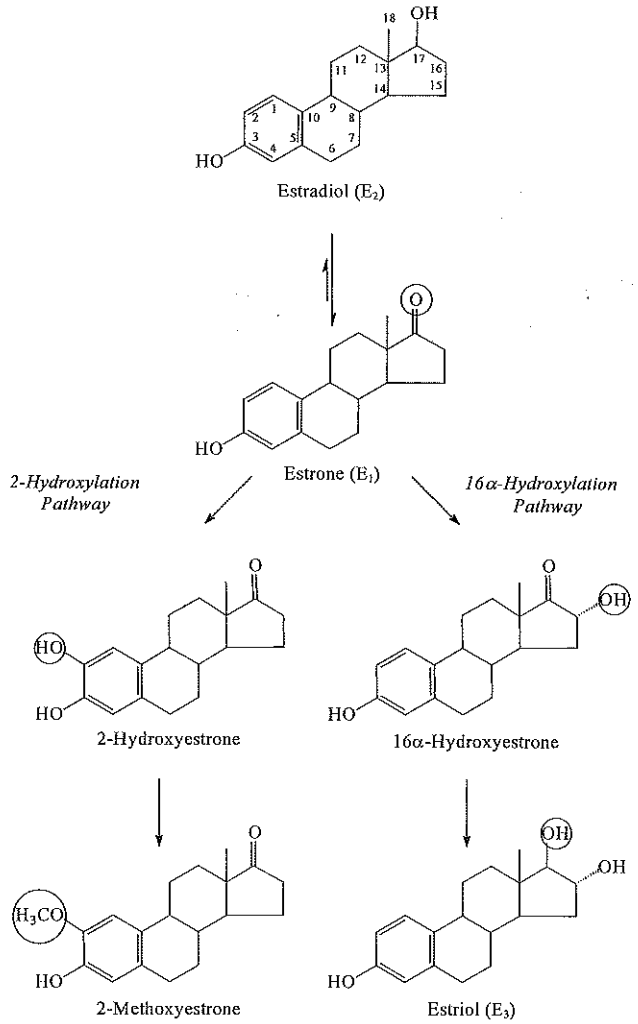

Figure 53-11 Main pathways of estradiol metabolism in humans. The *circled area* represents the site of chemical change.

then metabolized along two alternative pathways: the *2-hydroxylation pathway* leads to the formation of catechol estrogens (2-hydroxyestrone, 2-hydroxyestradiol, and 2-hydroxyestriol and their corresponding methoxy derivatives), and the *16α-hydroxylation pathway* leads predominantly to the formation of estriol.[46,373] The direction of estradiol metabolism depends on the pathophysiological state. For example, obesity and hypothyroidism are associated with an increase in estriol formation, whereas low body weight and hyperthyroidism are associated with the formation of catechol estrogens.[46] Although assays for catechol estrogen measurement are available,[56,220] they have no known current clinical value.

As is the case for other steroids, the liver is the primary site for the inactivation of estrogens. The main biochemical reactions are hydroxylation, oxidation, reduction, and methylation. Conjugation with glucuronic or sulfuric acid, which imparts more water solubility to these steroids and thus allows them to be eliminated rapidly through the kidney, is the final step in the metabolic process. Catechol estrogens, in addition, can bind covalently with protein through *o*-quinone or *o*-semiquinone intermediates.

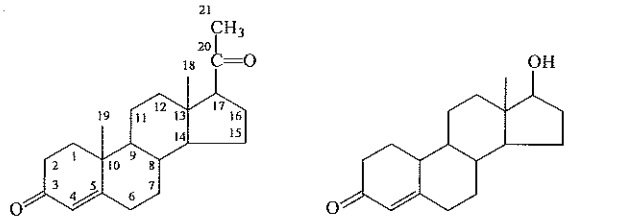

Figure 53-12 Structural formulas of progesterone and 19-nortestosterone.

PROGESTERONE

Progesterone, like the estrogens, is a female sex hormone. In conjunction with estrogens, it helps to regulate the accessory organs during the menstrual cycle.[373,376] This hormone is especially important in preparing the uterus for the implantation of the blastocyst and in maintaining pregnancy. In nonpregnant women, progesterone is secreted mainly by the corpus luteum. During pregnancy, the placenta becomes the major source of this hormone. Minor sources are the adrenal cortex in both sexes and the testes in men.

Chemistry

The structural formula of progesterone, a C_{21} compound, is shown in Figure 53-12. Like the corticosteroids and testosterone, progesterone (pregn-4-ene-3,20-dione) contains a keto group (at C-3) and a double bond between C-4 and C-5 (Δ^4); both structural characteristics are essential for progestational activity. The two-carbon side chain (CH_3CO) on C-17 is not thought to be important for its physiological action. Indeed the synthetic compound 19-nortestosterone (see Figure 53-12) and its derivatives, which are widely used as oral contraceptives, are more potent progestational agents than progesterone itself.

Biochemistry and Physiology

Biosynthesis

Biosynthesis of progesterone in ovarian tissue is believed to follow the same path from acetate to cholesterol through pregnenolone as it does in the adrenal cortex (see Chapter 51).[46,373,375] In luteal tissue, however, low-density lipoprotein cholesterol is thought to serve as the preferred precursor despite the potential of the corpus luteum to synthesize progesterone de novo from acetate.[306] Initiation and control of luteal secretion of progesterone are regulated by LH and FSH.[46,320,373]

Transport

Progesterone does not have a specific plasma-binding protein, but like cortisol is bound to corticosteroid-binding

globulin. Reported concentrations for plasma free progesterone vary from 2% to 10% of total concentrations, and the percentage of unbound progesterone remains constant throughout the normal menstrual cycle.[115] The production rate of progesterone during the luteal phase reaches as high as 30 mg/day, whereas the production rate of progesterone by the placenta during the third trimester of pregnancy is ~300 mg/day.

Metabolism

The important metabolic events leading to inactivation of progesterone are reduction and conjugation. The main metabolic pathway for the metabolism of progesterone is shown in Figure 53-13.

Metabolites of progesterone may be classified into three groups based on the degree of reduction:

1. ***Pregnanediones.*** The C4-5 double bond is reduced, producing two compounds: pregnanedione (hydrogen atom at C-5 is in β-orientation) and allopregnanedione (hydrogen atom at C-5 is in α-orientation).
2. ***Pregnanolones.*** The keto group at C-3 is reduced, producing hydroxyl groups in α- or β-orientation. However, most urinary pregnanolones exist in the α-configuration.
3. ***Pregnanediols.*** The keto group at C-20 is also reduced. As in the previous case, metabolites containing the 20-hydroxyl group in α-orientation are quantitatively more important. In fact, urinary measurement of pregnanediol (5β-pregnane-3α,20α-diol) can be used as an index of endogenous production of progesterone, because this metabolite is quantitatively very significant and its concentration correlates with most clinical conditions.

Reduced metabolites are eventually conjugated with glucuronic acid and excreted as water-soluble glucuronides.

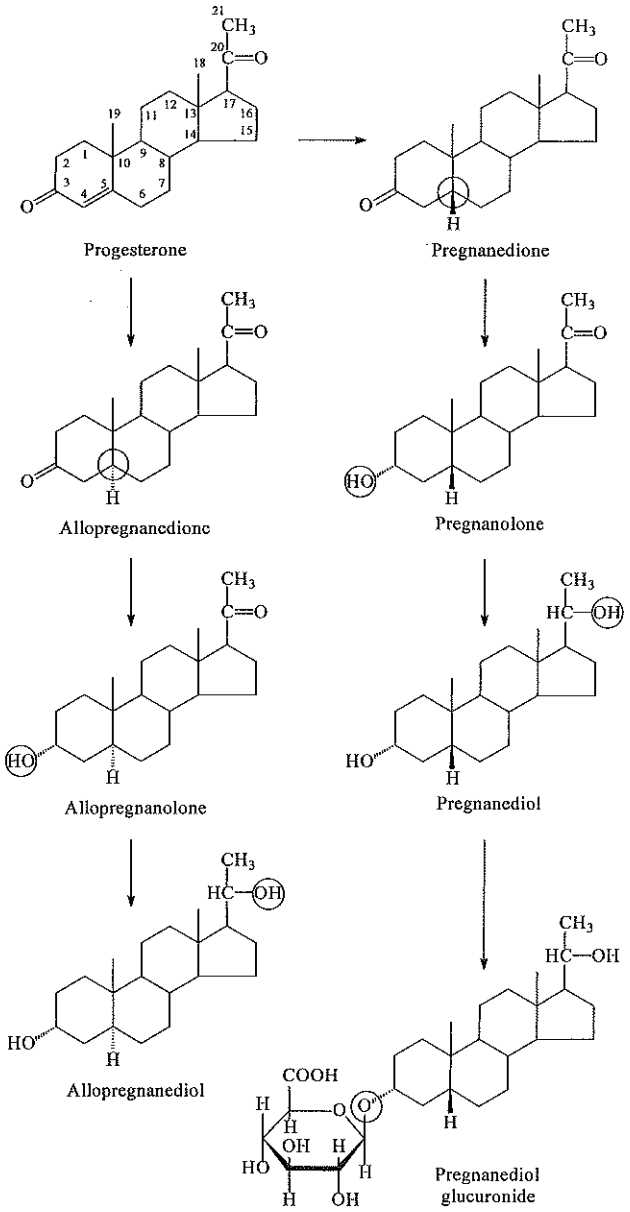

Figure 53-13 Metabolism of progesterone. The *circled area* represents the site of chemical change.

Female Reproductive Development

Fetal

In the genotypic female, lack of testosterone and MIS causes regression of the wolffian ducts and maintenance of the mullerian ducts, thus forming the female reproductive tract.[46,114] Gonadotropin activity in utero is suppressed because of high concentrations of circulating estrogens derived from the mother.[46,373]

Postnatal

When the placenta separates, concentrations of fetal sex steroids drop abruptly. Serum estradiol in neonates decreases to basal concentrations within 5 to 7days after birth and persists at this concentration until puberty. The negative feedback action of steroids is now removed, and gonadotropins are released. Postnatal peaks of LH and FSH are measurable for a few months after birth, peaking at 2 to 5 months and then dropping to basal concentrations.

During childhood, circulating concentrations of sex steroids and gonadotropins are low and are similar for both sexes. However, in patients with hypogonadism (Turner's syndrome), LH and FSH concentrations are higher than in normal children.[46,373] Pituitary response to exogenous GnRH stimulation parallels the endogenous secretion rates of LH and FSH. In children younger than 2 years of age, LH and FSH production increases dramatically in response to exogenous GnRH administration.[110] From then until about age 10, the responses are less than during the first 2 years. At the peripubertal stage, LH concentrations rise to more than 15 IU/L in both boys and girls, a response comparable with that in adults.[46,373] FSH response parallels that of LH, but is lesser in magnitude.

Puberty

The transition from sexual immaturity appears to begin with a diminished sensitivity of the pituitary gland or hypothal-

amus, or both, to the negative feedback effect of the sex steroids. The mechanism for this change is unclear. As puberty approaches, nocturnal secretion of gonadotropins occurs. Concentrations for LH, FSH, and gonadal steroids rise gradually over several years before stabilizing at adult concentrations, when full sexual maturity is reached. In girls, puberty is considered precocious if the onset of pubertal development (secondary sex characteristics) occurs before the age of 8 (see later section on precocious puberty), and delayed if there has been no development by the age of 13 or if menarche has not occurred by age 16.5.[69,227] Current literature reports that the median age of menarche in the United States is 12.43 years, which is 0.34 years earlier than reported in 1973.[60,213] This study also found that the median age at menarche of non-Hispanic black (12.06 years) girls is significantly earlier than that of non-Hispanic white (12.55 years) and Mexican-American (12.25 years) girls.[60]

Adrenarche precedes puberty by a few years. In girls, the rise in adrenal androgen concentrations (DHEA, DHEA-S, and androstenedione) begins at 6 to 7 years.[256] This rise in adrenal androgen concentrations lasts until late puberty. A cortical androgen-stimulating hormone may contribute to the rise of adrenal androgens at puberty in both sexes.[256] In girls, puberty is associated with rises in estrogen secretion by the ovary in response to gonadotropin concentrations that increase in response to GnRH.[30,46,307] Estrogen secretion by the ovary increases and causes enlargement of the uterus and breasts. In the breast, estrogen enhances growth of ducts; progesterone augments this effect. As the breast develops, estrogen also increases adipose tissue around the lactiferous duct system and contributes to the further enlargement of breast tissue.[46,373] The alveoli shift to a secretory pattern under the influence of progesterone.

Female Reproductive Abnormalities

Female Pseudohermaphroditism

In pseudohermaphroditism, the gonadal sex varies from the genital sex. The female pseudohermaphrodite is an individual who is genetically female but whose phenotypic characteristics are, to varying degrees, male. In neonates with a 46 XX karyotype and ambiguous genitalia, *congenital adrenal hyperplasia* (CAH) should be considered. CAH is a family of autosomal recessive disorders of adrenal steroidogenesis (see Chapter 51). Each disorder has a specific pattern of hormonal abnormalities resulting in deficiency or excess of androgens. The molecular genetics of CAH are discussed in detail in several reviews.[68,156,157,189,360] In female fetuses, exposure to androgens before the 12th week of gestation causes ambiguous genitalia; after 13 weeks, it results in clitoral enlargement.[46,293] Because androgen excess occurs before the 12th week of gestation in those with CAH, ambiguous genitalia are almost always present. Only deficiencies of 21-hydroxylase and 11β-hydroxylase are predominantly virilizing disorders. Deficiency of 3β-hydroxysteroid dehydrogenase is rare, but when present, affected girls may exhibit virilization.

Diagnosis of *21-hydroxylase deficiency* can be made in infants and children with excess excretion of urinary 17-KSs and pregnanetriol (a metabolite of 17-hydroxyprogesterone; see Chapter 51) and an elevated concentration of plasma 17-hydroxyprogesterone and androstenedione.[136,157,241] However, sick and premature infants may have elevated concentrations of 17-hydroxyprogesterone and androstenedione.[136,157] An elevation of 17-hydroxyprogesterone concentrations in early infancy (>3000 ng/dL) confirms the diagnosis of this disorder.[136,350] Additionally, molecular diagnostic testing is now available for detection of the mutations that account for a majority (80% to 90%) of 21-hydroxylase deficiency cases.[315]

An *11β-hydroxylase deficiency* is confirmed by finding elevated plasma concentrations of 11-deoxycortisol and deoxycorticosterone, increased concentrations of their metabolites in urine, and their suppression by glucocorticoid therapy (see Chapter 51). Plasma renin activity and aldosterone concentrations are low in this deficiency.[136,189,259]

Elevated plasma concentrations of 17-hydroxypregnenolone, DHEA, and DHEAS are found in patients with *3β-hydroxysteroid dehydrogenase deficiency* (see Chapter 51). Plasma concentrations of 17-hydroxyprogesterone may be elevated due to peripheral conversion of 17-hydroxypregnenolone. The ratio of 17-hydroxypregnenolone to 17-hydroxyprogesterone is strikingly elevated in these patients.[136,189,252]

Precocious Puberty

Precocious puberty is the development of secondary sexual characteristics in girls less than 8 years old and boys less than 9 years old.[276] In 1999, the Lawson Wilkins Pediatric Society issued new recommendations to lower the age standards at which puberty should be considered precocious from 8 to 7 in white girls and to 6 in black girls.[173] The new recommendations were met with criticism because they are based solely on a single epidemiological study performed by Herman-Giddens and collaborators in 1997.[151] Many argue that the decreased age standards will result in underdiagnosis of this condition.[197,225,278]

Despite the debate over the age of onset, pediatric endocrinologists agree that it is important to distinguish between benign advanced pubertal conditions and true precocious puberty.* Early puberty is manifested by the appearance of secondary sexual characteristics such as premature thelarche (premature breast development), premature adrenarche (premature sexual hair development), or phallic enlargement. When presented as isolated cases, these secondary sexual characteristics are not considered to be pathological as none progresses to full-blown puberty, nor are they associated with increased rates of bone growth and maturation. However, if a child has at least two signs of puberty and also demonstrates increased rates of bone growth and

*References 48, 166, 182, 192, 196, 224.

maturation, the many causes of true precocious puberty must be considered.[224]

Precocious puberty is classified as GnRH dependent or independent.[48,166,182,224] GnRH-dependent precocious puberty (also called central precocious puberty) is due to precocious activation of the hypothalamic-pituitary-gonadal axis. In girls, the cause is most commonly idiopathic (90%); however, idiopathic cases account for less than 10% of central precocious puberty in boys. Central nervous system tumors can also cause central precocious puberty, the most common being hypothalamic hamartomas. Neurofibromatosis has been also reported to lead to GnRH-dependent precocious puberty.

GnRH-independent precocious puberty (also called pseudoprecocious puberty) refers to precocious sex steroid secretion that is independent of pituitary gonadotropin release. CAHs is a common cause of pseudoprecocious puberty. Classic forms of CAH present with virilization, growth acceleration, and accelerated bone maturation. Nonclassical or late-onset forms usually present in childhood or adolescence with premature adrenarche and acne. In fact, 5% to 10% of children presenting with premature adrenarche have late-onset adrenal hyperplasia. Tumors of the adrenal gland, ovaries, and testes that secrete androgens or estrogens may result in GnRH-independent precocious puberty. Males exhibiting signs of puberty around age 2 are characteristic of testotoxicosis, a familial male-limited form of precocious puberty. This autosomal dominant disorder is due to activating mutations affecting LH receptors. The McCune-Albright syndrome is due to a point mutation in the G protein associated with gonadotropin receptors, which causes the gonads to function as if both the FSH and LH receptors are constitutively activated. Although this mutation results in GnRH-independent precocious puberty in both sexes, it is most common in girls. Precocious puberty combined with polyostotic fibrous dysplasia and café-au-lait pigmentation are hallmarks for McCune-Albright syndrome. Severe hypothyroidism is also associated with GnRH-independent precocious puberty, likely due to the intrinsic FSH activity of high circulating concentrations of TSH. Unlike the other causes, hypothyroid-induced precocious puberty is associated with skeletal and growth delay.

Diagnosis of precocious puberty is based on (1) clinical presentation, (2) a thorough pubertal history, (3) bone age determinations, and (4) laboratory tests to assess gonadotropin concentrations and response to exogenous GnRH.* The GnRH stimulation test is the gold standard for diagnosis of GnRH-dependent precocious puberty. Pubertal responses of LH and FSH to GnRH stimulation are considered diagnostic of precocious puberty when the chronological age is inappropriate for the hormone response. The GnRH stimulation test is also used to monitor the effectiveness of GnRH agonist therapy.[190,288,289] Typically, an IV bolus of exogenous GnRH is administered followed by a single measurement (at 40 to 45 minutes) or serial measurements of LH and FSH concentrations.* A predominant LH response correlates with a pubertal pattern and cutoffs vary depending on the assay, with sex differences noted. A typical pubertal response is characterized by a rise in LH ≥8 IU/L after IV administration of 100 μg GnRH.[227] In girls, peak LH/FSH ratios >0.66 to 1.0 have also been proposed to be diagnostic of central precocious puberty.[247,348] Highly sensitive fluorometric[37] and chemiluminetric[240] immunoassays are now available for measuring basal LH concentrations. Basal LH concentrations can be used instead of the GnRH stimulation test for diagnosis of central precocious puberty. A fluorometric assay resulting in a basal concentration of LH >0.6 IU/L in either sex indicates a pubertal pattern and is consistent with precocious puberty. Values <0.6 IU/L can occur with any form of precocious puberty and require follow-up with a GnRH stimulation test.[37] A similar pattern is observed for the immunochemiluminometric assays using a cutoff of 0.3 IU/L.[239,240]

Response to exogenous GnRH is suppressed and LH and FSH concentrations are low in individuals with GnRH-independent precocious puberty. The diagnosis of GnRH-independent precocious puberty must exclude nonclassical adrenal hyperplasia (NCAH). Basal 17-hydroxyprogesterone concentrations of early morning samples can be used to screen for 21-OH-deficient NCAH. A basal 17-hydroxyprogesterone concentration <200 ng/L (<6.0 nmol/L) almost always rules out 21-OH-deficient NCAH. Patients with intermediate (200 to 500 ng/dL) basal 17-hydroxyprogesterone concentrations should undergo an ACTH stimulation test to confirm the presence of a 21-OH-deficient NCAH. Such a test is done by measuring the 17-hydroxyprogesterone response to ACTH stimulation. An exaggerated response is expected in cases of NCAH. Although controversial, current guidelines use a 17-hydroxyprogesterone diagnostic cutoff of >1000 ng/dL (>30 nmol/L).[242] Some argue that the cutoff should be raised to >1500 ng/dL (>45 nmol/L) or >2000 ng/dL (>60 nmol/L), as the value of 30 nmol/L was set before the availability of molecular genotyping, and studies have indicated that several nonaffected carriers exhibit 17-hydroxyprogesterone concentrations above 30 nmol/L.[7,8,10]

The therapy for precocious puberty is dependent upon the presenting symptoms and underlying causes.[182,192,196,224,257] Isolated premature thelarche or adrenarche does not require therapy. Patients with premature thelarche should be followed for 3 to 6 months and require further evaluation for precocious puberty. Cases of premature adrenarche should be evaluated for NCAH and/or polycystic ovary syndrome (PCOS) in girls with determined insulin resistance. GnRH-dependent precocious puberty is

*References 48, 166, 182, 192, 196, 224.

*References 53, 100, 166, 183, 195, 239, 240.

treated using GnRH agonists to inhibit normal gonadotropin release, thereby slowing pubertal progression. The therapy for GnRH-independent precocious puberty is determined by the underlying cause.

Estrogens and Breast Cancer

Suspicions of estrogen-based etiologies in the development of human breast cancer result from both epidemiological and experimental observations.[99A,159,211,233A] Early menarche and later natural menopause are associated with increased risk of breast cancer. A two-stage mechanism has been postulated: (1) initiation of a precancerous state by ovarian activity during the early reproductive years, and (2) continuation of ovarian activity in later years as a promoting influence on already initiated tumor cells. Ovarian estrogen has been assumed to be the causative factor, as the administration of estrogen negates the protective effects of early oophorectomy. Moreover, treatment of men with estrogen for prostatic cancer or after transsexual operations is also associated with an increased risk of breast cancer.

Low risk for breast cancer has consistently been connected with high parity. Increased risk is associated with early menarche, late (>30 years) first full-term pregnancy, and late menopause. Pregnancy occurring before age 25 to 30 years has a protective effect.

According to the theory, the relative concentrations of individual estrogen fractions (estrone, estradiol, and estriol) produced in the first decade or so after puberty are important determinants of a woman's lifetime risk of breast cancer.[63] In particular, pregnancy at a young age is associated with both favorable estrogen fraction ratios and decreased risk. Further discussion of the role of estrogen in the genesis of breast cancer is found in monographs and review articles.[62,144-146,175,176,204]

The rationale for using endocrine therapy in women with breast carcinoma is based on the fact that estrogen stimulates biochemical processes in cells of the uterus, pituitary gland, hypothalamus, and breast that normally contain the estrogen receptor. A reduction in circulating estrogen concentrations would be expected to decrease the biochemical activity of these cells. Approximately one third of women with metastatic breast carcinoma obtain an objective remission after various types of endocrine therapy directed at lowering their estrogen concentrations. Such therapy includes oophorectomy, hypophysectomy, and adrenalectomy (ablative therapy), and administration of antiestrogens, androgens, and aromatase inhibitors (additive therapy).[22,42,188,274]

Cytoplasmic estrogen receptors are important prognostic indicators and are now routinely measured in samples of breast tissue after surgical removal of the tumor. Sixty percent of patients with carcinoma of the breast have tumors that are estrogen receptor positive. Approximately two thirds of patients with estrogen receptor–positive tumors respond to endocrine therapy; 95% of the patients with estrogen receptor–negative tumors fail to respond. Therefore, the greater the estrogen receptor content of the tumor, the higher the response rate to endocrine therapy and lower incidence of recurrence.

Normal Menstrual Cycle

During a normal menstrual cycle, there is a closely coordinated interplay of feedback effects between the hypothalamus, the anterior lobe of the pituitary gland, and the ovaries. In addition, there are cyclic hormone changes that lead to functional and structural changes in the ovaries (follicle maturation, ovulation, and corpus luteum development), uterus (preparation of the endometrium for possible implantation of the fertilized ovum), cervix (to permit transport of sperm), and vagina (see Figure 53-7).[46,373,376]

Phases

The menstrual cycle is measured beginning with day 1 as the first day of menstrual bleeding. Each cycle consists of a follicular and a luteal phase.

Follicular Phase

The *follicular phase,* the initiation of follicular growth, actually begins during the last few days of the previous luteal phase and terminates at ovulation (see Figure 53-7). During the early part of the follicular phase, concentrations of FSH are elevated, but decline up until ovulation (Figure 53-7).[46] LH secretion begins to increase around the middle of the follicular phase. Just before ovulation, estrogen secretion by the follicle increases dramatically, which positively stimulates the hypothalamus and triggers the LH surge. The LH surge is a reliable predictor of ovulation, with the onset of the surge occurring 24 to 36 hours and the peak occurring 10 to 12 hours before ovulation.[46] Ovulation occurs around day 14 of the menstrual cycle.

Luteal Phase

The *luteal phase* is the last half of the cycle and is characterized by increasing production of progesterone and estrogen from the corpus luteum with consequent gradual lowering of LH and FSH concentrations. Progesterone reaches a peak of approximately 8 mg/day at about 8 days postovulation. If ovulation does not occur, the corpus luteum fails to form, and a cyclical rise in progesterone is subnormal. If pregnancy occurs, hCG maintains the corpus luteum and progesterone continues to rise. In the absence of conception, the corpus luteum resolves and results in a decrease in estrogen and progesterone concentrations and a breakdown of the endometrium. The average duration of menstrual flow is 4 to 6 days and average menstrual blood loss is 30 mL.[46]

Role of Individual Hormones

To explain further the intricacies of the normal menstrual cycle, the fluctuations of each major hormone are discussed separately in the following sections with regard to control and effects (see also Figures 53-7 and 53-14).

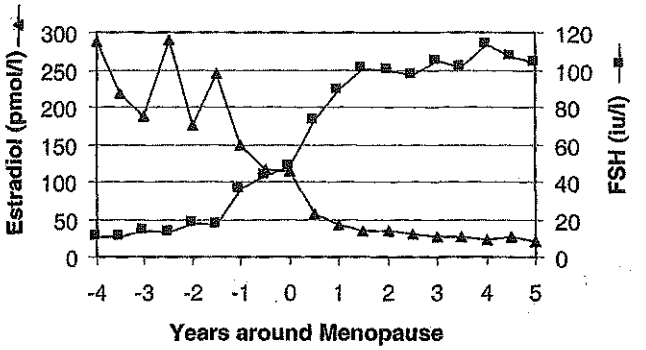

Figure 53-14 Geometric means for FSH and estradiol in relation to the final menstrual period (FMP). The horizontal axis represents time (yr) with respect to the FMP (0); negative (positive) numbers represent time before (after) the FMP. *(From Burger HG, Dudley EC, Hopper JL, Groome N, Guthrie JR, Green A, et al. Prospectively measured levels of serum follicle-stimulating hormone, estradiol, and the dimeric inhibins during the menopausal transition in a population-based cohort of women. J Clin Endocrinol Metab 1999;84:4025-30; Figure 1A.)*

Gonadotropin-Releasing Hormone

Gonadotropin-releasing hormone triggers the surge of LH that precedes ovulation.[46,373,376] There appear to be two separate feedback centers in the hypothalamus: a tonic negative feedback center in the basal medial hypothalamus and a cyclical positive feedback center in the anterior regions of the hypothalamus. Low concentrations of estradiol, such as those that are present during the follicular phase, affect the negative feedback center, whereas high concentrations of estradiol, such as are seen just before the midcycle LH peak, trigger the positive feedback center. Progesterone, in combination with estrogen, affects the negative feedback center in the luteal phase. GnRH is released in a pulsatile fashion and has a self-priming effect; the first dose potentiates the effect of subsequent doses. The magnitude of the LH response to GnRH increases steadily through the follicular phase and is greatest at the time of the preovulatory surge of LH, after which it declines again.

Follicle-Stimulating Hormone

A few days before day 1 of the cycle, FSH shows a slight but important peak (see Figure 53-7), probably triggered by a fall in estradiol concentration that briefly eliminates the negative feedback effect.[46,373,376] This peak of FSH initiates the growth and maturation of a cohort of ovarian follicles. LH and FSH release are pulsatile throughout the cycle. As estrogen is released from the growing follicles, FSH concentrations fall again and remain low through the follicular phase. By days 5 to 7, a single follicle is selected for further growth. The effect of FSH on the maturing follicle is increased through estradiol-induced changes in FSH receptors. FSH, aided by estradiol, acts on the cells of the follicle to increase responsiveness of LH receptors by the time of midcycle surge. FSH and LH receptors respond with an increase either in their number or in their affinity for corresponding gonadotropin. There is a rise in FSH at midcycle that is triggered by progesterone. The function of this peak is not entirely known, but is thought to stimulate plasminogen activator and increase granulosa cell LH receptors.[46] During the luteal phase, FSH is suppressed by negative feedback from estradiol until a lesser FSH peak, occurring near the end of the cycle, starts off the follicular maturation of the next cycle.

Luteinizing Hormone

Luteinizing hormone secretion is suppressed in the follicular phase by negative feedback from estradiol.[46,373,376] As estradiol production by the developing follicle increases, the effect of estradiol on the positive feedback center becomes important. Increasing release of GnRH from the hypothalamus and increasing sensitivity of the anterior lobe of the pituitary gland to GnRH result in the midcycle surge of LH. Ovarian follicle receptors for LH, sensitized by FSH and estradiol, transmit the stimulus to enhance differentiation of the theca cell and the production of progesterone by the developing corpus luteum. LH production is suppressed during the luteal phase by negative feedback from progesterone combined with estradiol, but a low concentration of LH is probably necessary to prolong corpus luteum function.

Estradiol

Estradiol production by the ovary falls near the end of a cycle, but begins to increase again under the influence of FSH (see Figure 53-7).[46,373,376] Estradiol enhances the FSH effect on a maturing follicle through changes in FSH receptors of the follicular cells, but suppresses pituitary FSH and LH release during the follicular phase through negative feedback. Before the midfollicular phase, estrogen concentrations are <50 pg/mL, but rise rapidly as the follicle matures. Estradiol production increases, reaching a midcycle peak between 250 and 500 pg/mL.[318] Estradiol concentrations fall off abruptly after ovulation, but rise again as the corpus luteum forms, reaching concentrations of approximately 125 pg/mL during the luteal phase.[318] Progesterone produced by the corpus luteum, combined with estrogen, exerts a negative effect on the hypothalamus and anterior lobe of the pituitary gland. As a result, LH and FSH secretion is suppressed again during the luteal phase. Estradiol is essential for the development of proliferative endometrium and is synergistic with progesterone for the development of the changes in the endometrium that initiate shedding; the decrease in negative feedback from estradiol on the anterior lobe of the pituitary gland triggers the FSH surge that begins the development of an ovarian follicle for the next cycle.

Changes in androgen production also occur during the menstrual cycle, with a peak at midcycle. Estradiol is not the only estrogen produced; estrone secretion, mainly from

peripheral sources, also increases throughout the cycle. Estrogen and progesterone have visible effects on vaginal cytology and cervical mucus, and progesterone elevates body temperature (as discussed later).

Progesterone

Progesterone is not produced in significant amounts until the midcycle LH surge and ovulation. LH enhances theca cell differentiation and progesterone production, which increase by a factor of 10 to 20, to a maximum about 8 days after the midcycle peak of LH. Progesterone is thought to stimulate the ovulatory peak of FSH and promote the growth of secretory endometrium, which is necessary for implantation of the fertilized ovum.[46]

Ovulation

An intricate interplay of endocrine events contributes to follicular maturation. Growth of ovarian follicles appears to be continuous. How an individual follicle is singled out for each menstrual cycle is not known. The late-cycle peak of FSH is likely important in this process. Once a follicle has been stimulated, estradiol production causes that specific follicle to be more receptive to effects from FSH. The high concentration of estradiol just before midcycle is responsible for triggering the positive feedback in the hypothalamus that leads to the midcycle LH surge. The precise cause of ovulation is not known, but ovulation occurs 1 to 24 hours after the LH peak. After ovulation, LH is suppressed by progesterone and estradiol, but the effect of LH is increased on the corpus luteum.[46,320,373,376] In the event of successful fertilization and implantation, corpus luteum function is sustained by hCG produced by the trophoblastic cells of the developing embryo. hCG has high molecular homology to LH and is capable of binding and stimulating LH receptors. Otherwise, the declining concentration of estradiol leads to regression of the corpus luteum and to the late-cycle FSH peak that starts the process again.

Irregular Menses

In a normal ovulatory menstrual cycle, menstruation occurs every 28 days on average. Normal women display considerable variation in cycle length that varies from 25 to 30 days.[46] Amenorrhea, the absence of menstrual bleeding, is traditionally categorized as either primary (women who have never menstruated) or secondary (women in whom menstruation is present for a variable time and then ceases). Amenorrhea is a relatively common disorder, with an estimated prevalence of 5% in the general population and as high as 8.5% in an unselected adolescent postpubescent population.[215]

Primary Amenorrhea

Primary amenorrhea (Box 53-2) is defined as a failure to establish spontaneous periodic menstruation by the age of 16 regardless of whether secondary sex characteristics have developed.[69,178,221] About 40% of phenotypic females who have primary amenorrhea (nearly always associated with absence of development of secondary sex characteristics) have *Turner's syndrome* (55 X karyotype) or *pure gonadal dysgenesis* (either 46 XX or XY karyotype).[46,375] *Mullerian duct agenesis* or *dysgenesis* with absence of the vagina or uterus is the second most common manifestation, and the third most common is *testicular feminization* (androgen receptor deficiency and normal or elevated plasma testosterone concentrations if the patient is past puberty and is karyotype XY).

A *17α-hydroxylase deficiency* is a rare form of CAH that is associated with delayed puberty, primary amenorrhea, and hypertension. These patients have a 46 XX karyotype with elevated gonadotropins, low sex steroids, hypertension, and hypokalemia (see Chapter 51).[69,189]

Another rare cause of amenorrhea is the so-called *resistant ovary syndrome.* This primary hypogonadal condition is associated with increased concentrations of plasma FSH and LH, and ovaries that contain predominantly primordial follicles. It is thought to arise from a defect in FSH receptors.[46] This disorder can be diagnosed only by examination of an ovarian biopsy specimen, which will exhibit functioning ovarian follicles despite the presence of amenorrhea. Ovulation can sometimes be induced in these patients with administration of high doses of gonadotropins.

As discussed earlier, *Kallmann's syndrome* involves hypogonadotropic hypogonadism associated with anosmia or hyposmia and is caused by a defect in the formation and migration of GnRH neurons. Sexual infantilism is the prominent manifestation and primary amenorrhea is common.[46,375] Finally, delayed pubertal development also should be considered.

Secondary Amenorrhea

Secondary amenorrhea is defined as an absence of periodic menstruation for at least 6 months in women who have previously experienced menses, or for 12 months in a woman with prior oligomenorrhea.[70,178,221,270,352] *Oligomenorrhea* is infrequent menstruation, occurring less than nine times per year.[279] With a few exceptions, the causes of primary and secondary amenorrhea overlap (see Box 53-2). Pregnancy is the most common cause of secondary amenorrhea and must be considered first and ruled out.[178,221,352] Elevated prolactin, either iatrogenic or induced by a prolactin-secreting tumor, can result in oligomenorrhea or amenorrhea.[178,221,352] About one third of women with no obvious cause of amenorrhea have elevated prolactin concentrations.[178] It is thought that hyperprolactinemia inhibits the release of LH and FSH.[184] Both hyperthyroidism and hypothyroidism are associated with a variety of menstrual disorders because of their effect on metabolism and interconversion of androgens and estrogens.[178,221,373]

Often it is helpful to separate patients with secondary amenorrhea into those with and without signs of hirsutism and androgen excess.

BOX 53-2 Causes of Amenorrhea

Primary Amenorrhea
- Lower tract defects
  - Vaginal aplasia
  - Imperforate hymen
  - Congenital vaginal atresia
- Uterine disorders
  - Congenital absence of the uterus
  - Endometritis
  - Mullerian agenesis (Mayer-Rokitansky-Kuster-Hauser syndrome)
- Ovarian disorders
  - XO gonadal and X dysgenesis and variants
  - XX gonadal dysgenesis
  - Turner's syndrome
  - Testicular feminization syndrome
  - 17-Hydroxylase deficiency of the ovaries and adrenal glands
  - Autoimmune oophoritis
  - Resistant ovary syndrome
  - Polycystic ovary syndrome
- Adrenal disorders (congenital adrenal hyperplasia)
- Thyroid disorders (hypothyroidism)
- Pituitary-hypothalamic disorders
  - Hypopituitarism
  - Constitutional delay in the onset of menses (physiological)
  - Nutritional disorders
  - Kallmann's syndrome

Secondary Amenorrhea
- Pregnancy/lactation
- Uterine disorders
  - Posttraumatic uterine synechiae (Asherman's syndrome)
  - Progestational agents
- Ovarian disorders
  - Polycystic ovary syndrome (hypothalamic)
  - Ovarian tumors
  - Premature ovarian failure (idiopathic, autoimmune, injury)
  - Antimetabolite therapy
- Adrenal disorders
  - Late-onset adrenal hyperplasia
  - Cushing's syndrome
  - Virilizing adrenal tumors
  - Adrenocorticoid insufficiency
- Thyroid disorders
  - Hypothyroidism
  - Hyperthyroidism
- Pituitary disorders
  - Acquired hypopituitarism (trauma, tumors, Sheehan's syndrome, lymphocytic hypophysitis)
  - Physiological or pathological hyperprolactinemia
- Hypothalamic disorders
  - Tumors and infiltrative diseases
  - Nutritional disorders
  - Hypophysitis
  - Excessive exercise
  - Stress
- Iatrogenic
  - Antipsychotics (phenothiazines, haloperidol, clozapine, pimozide)
  - Antidepressants (tricyclics, monoamine oxidase inhibitors)
  - Antihypertensives (calcium channel blockers, methyldopa, reserpine)
  - Drugs with estrogenic activity (digitalis, flavonoids, marijuana, oral contraceptives)
  - Drugs with ovarian toxicity (busulfan, chlorambucil, cisplatin, cyclophosphamide, fluorouracil)

Androgen Excess

A patient with androgen excess can present with variable degrees of excess hair on the face, chest, abdomen, and thighs, acne, and obesity. Amenorrhea caused by androgen excess can be due to adult-onset CAH, corticotropin-dependent Cushing's syndrome, or PCOS.

Some individuals with 21-hydroxylase deficiency do not manifest any developmental abnormalities or salt wasting, but they present with signs of androgen excess. This clinical syndrome, referred to as *nonclassic, adult-onset,* or *late-onset CAH,* may be indistinguishable from PCOS (see also Chapter 50).[7,80,116]

PCOS occurs in about 5% to 10% of premenopausal women and is thought to be caused by a hypothalamic disorder.[46,126,316,377] PCOS is clinically defined by hyperandrogenism with chronic anovulation in women without underlying disease of the adrenal or pituitary glands.[116,201] This syndrome is characterized by infertility, hirsutism, obesity (in approximately half of those affected), and various menstrual disturbances ranging from amenorrhea to irregular vaginal bleeding (Table 53-1). Although this syndrome is associated with polycystic ovaries, this has not been considered essential for the diagnosis. The name is actually a misnomer, as the ovaries are covered with follicles not cysts. Women with PCOS have a greater frequency of both hyperinsulinemia and insulin resistance.[98,116,202,260,317] As a result, acanthosis nigricans (dark pigmentation of the spiny layer of the skin) is sometimes present in obese women with PCOS.[99] Relatively low FSH concentrations and disproportionately high LH concentrations are common in PCOS. Serum androstenedione and testosterone concentrations (total and free concentrations) are elevated, with mean concentrations 50% to 150% higher than normal.[19,46,116] PCOS patients have substantial estrogen production because of the peripheral conversion of androgens to estrogens. The anovulation is caused by continuous estrogen stimulation of the endometrium. This chronic stimulation may predispose these patients to endometrial cancer.[116] There has been some attempt to link PCOS to *leptin,* a hormone that is secreted by adipocytes and thought to play a role in regulating food

TABLE 53-1 Clinical Features of the Polycystic Ovary Syndrome

Clinical Feature	Frequency (%)
Hirsutism	65
Acne	26
Obesity	37
Infertility	48
Amenorrhea	35
Oligomenorrhea	42
Regular menstrual cycle	20

Data were compiled from three studies. Two used ultrasonography as the primary method of diagnosis, one used ovarian histology. Total $N = 1935$. Modified from Franks S. Polycystic ovary syndrome. N Engl J Med 1995;333. Copyright 1995 Massachusetts Medical Society. All rights reserved.

intake and metabolism.[39] Animals that lack leptin are infertile, and leptin injection increases gonadotropin secretion and restores fertility.[15,58] However, literature suggests that leptin concentrations are normal in patients with PCOS.[45] In a 2001 report, Veldhuis and collaborators note that although the serum leptin concentrations were the same in PCOS patients and controls, the pattern of leptin secretion was abnormal in girls with PCOS.[343]

Ovarian hyperthecosis, a nonneoplastic lesion of the ovary characterized by the presence of islands of luteinized thecal cells in the ovarian stroma, is sometimes confused with PCOS. The features that distinguish it from PCOS include higher concentrations of testosterone, androstenedione, and DHT derived from ovarian secretion. Thus there is greater androgenization than is usually observed in patients with PCOS. Estrone secretion is greater, and both LH and FSH concentrations are either reduced or less than normal. Insulin resistance and hyperinsulinism are present to a greater degree than in PCOS. Finally, patients with ovarian hyperthecosis fail to ovulate when treated with an antiestrogen, such as clomiphene citrate.[377]

Hirsutism and Virilization

Hirsutism is defined as the excessive growth of terminal hair in women and children in a distribution similar to that occurring in postpubertal men.[6,275,287] True hirsutism, which is androgen responsive, has to be distinguished from hypertrichosis, which is excessive growth of vellus or non–androgen-responsive hair. Vellus is fine, downy hair, which is usually unpigmented, whereas terminal hairs are thick and found in androgen-responsive areas of the skin.[280,287] Growth of vellus hair diffusely over the trunk and face is either familial or drug induced, and can be treated only by mechanical hair removal or withdrawal of the inducing drug. Women with androgen-dependent hirsutism either have exposure to excess androgens or have a heightened sensitivity to normal circulating concentrations of androgen. As a consequence, the vellus follicles develop into terminal hair follicles in the areas of androgen-sensitive skin.

BOX 53-3 Causes of Hirsutism

Ovarian
- Severe insulin resistance
- Hyperthecosis, hilus cell or stromal cell hyperplasia
- Androgen-producing ovarian tumors
- Menopause

Adrenal
- Classical congenital hyperplasia
  - 21-Hydroxylase deficiency
  - 11-Hydroxylase deficiency
  - 3β-Hydroxysteroid dehydrogenase deficiency
- Adult or attenuated adrenal hyperplasia
- Androgen-producing adrenal tumors

Familial Hirsutism

Endocrine Disorders
- Polycystic ovary syndrome
- Hyperprolactinemia
- Acromegaly
- Cushing's syndrome

Idiopathic Hirsutism (includes increased skin sensitivity to androgens)

Iatrogenic
- Androgens
- Dilantin
- Diazoxide
- Minoxidil
- Streptomycin
- Cyclosporine
- Danazol
- Metyrapone
- Phenothiazides
- Progestogens (19-norsteroid derivatives)

Causes of hirsutism are listed in Box 53-3. The estimated prevalence for idiopathic hirsutism ranges from 6% to 50% of women evaluated for hirsutism depending on the definition.[9,44,287,291] Typically, idiopathic hirsutism is defined by normal physical and laboratory findings in hirsute women. However, Azziz and collaborators report that the prevalence of idiopathic hirsutism changes drastically whether or not factors such as ovulatory function and androgen concentrations are considered.[9] It is thought that an increased sensitivity of the hair follicle to normal circulating androgens causes the excess hair growth.[287] Nonneoplastic forms of hirsutism are slow to progress and usually manifest at the time of puberty, when circulating concentrations of androgens increase, or after a period of weight gain, or when oral contraceptives have been stopped.[275] A rapid onset of hirsutism

suggests an iatrogenic cause, or if associated with virilization, a neoplastic source of androgens. The most common cause of androgen hypersecretion in women is PCOS, with a reported 70% to 80% of hirsute women affected with this disorder.[291] The hyperandrogenism usually arises from both ovaries and the adrenal glands (for more on PCOS, see previous section). Late-onset CAH (see Chapter 51), acromegaly, hyperprolactinemia, menopause (see also section on menopause, later in this chapter), and adrenocorticotropic hormone (ACTH)–dependent Cushing's syndrome can also cause hirsutism.

Virilization is characterized by clitoral hypertrophy, deepening of the voice, temporal hair recession, baldness, increased libido, decreased body fat, and menstrual irregularities or amenorrhea. Hirsutism is usually associated with normal or slightly elevated serum androgens, whereas virilization is associated with marked increases in ovarian or adrenal androgen production.[46]

The role of the laboratory in evaluation of women for hirsutism and virilization is discussed in a later section on tests for the evaluation of amenorrhea in this chapter.

Other Factors

Many other factors or conditions will cause secondary amenorrhea. They include disorders of the ovary, uterus, pituitary, and hypothalamus, and drugs.

Disorders of the ovary such as premature ovarian failure (POF) and loss of ovarian function can cause amenorrhea. *POF* has been defined as failure of ovarian estrogen production occurring in a hypergonadotropic state at any age between menarche and age 40.[46,70,178,352] If the patient is younger than 25 years of age, karyotyping should be performed to rule out the presence of a variety of chromosomal abnormalities involving duplications or absence of the X chromosome or presence of a Y chromosome. Patients present with symptoms of hypoestrogenism, including hot flashes and high gonadotropin concentrations. Autoimmune disorders have been associated with 20% to 40% of cases of POF that result in destruction of the ovary and in amenorrhea.[46,70,178,352] These patients also may have antibodies to other endocrine and nonendocrine tissue. Other causes for ovarian failure include oophorectomy, cystic degeneration, trauma, infection, or interference with blood supply. In rare patients, there may be evidence of ovarian resistance to gonadotropins.[46,353]

Secondary amenorrhea also is caused by uterine failure. The patient with a uterine problem is normal hormonally, but does not menstruate. *Asherman's syndrome,* or intrauterine adhesions, is the most common outflow-tract abnormality that causes amenorrhea. Endometrial damage may occur in response to a dilatation and curettage and to infections of the endometrium.[70,178] Pituitary dysfunction can cause secondary amenorrhea. This is most often caused by intrinsic pituitary tumors. However, Sheehan's syndrome and pituitary apoplexy can also result in hormone deficiency. Empty sella syndrome has been reported in 4% to 16% of patients with amenorrhea and galactorrhea.[178]

Hypothalamic dysfunctions consist of those disorders that disrupt the frequency or amplitude of GnRH. Rarely, this can be caused by a lesion or tumor. However, most commonly, disruption occurs in response to psychological stress, depression, severe weight loss, anorexia nervosa, or strenuous exercise.[70,178] A syndrome known as the *female athletic triad* has also been described. This syndrome is prevalent in women who exercise vigorously, and is associated with amenorrhea, disordered eating, and osteoporosis. Competitive long-distance runners, gymnasts, and professional ballet dancers appear to be at highest risk. Although the mechanism for the disturbance is unclear, the symptoms and laboratory profiles are similar to those of other forms of hypothalamic amenorrhea. LH and FSH concentrations are normal or low, and estradiol concentrations are low. As a result of the chronic low estrogen, bone mineral content is low and the incidence of stress fractures is increased.[70,215]

Several tumors of the ovary, pituitary gland, and adrenal glands occur in combination with amenorrhea.[46,209,339,375] The amenorrhea may be confused with pregnancy if the tumors produce hCG. Choriocarcinomas of the uterus or ovary may produce large amounts of hCG that can cause hyperthyroidism because of the slight thyrotropic action of hCG. Granulosa–theca cell tumors are usually associated with estrogen secretion that results in amenorrhea and irregular menses and, rarely, excessive androgen with associated virilization.[46,375]

Many drugs can also produce amenorrhea (see Box 53-2), particularly phenothiazines and other psychotropic drugs such as haloperidol, pimozide, or clozapine.[178] The phenothiazine-induced amenorrhea is usually associated with hyperprolactinemia and galactorrhea. Drugs affecting the normal pathway of dopamine secretion can produce amenorrhea by decreasing the secretion of norepinephrine. Because norepinephrine is important in controlling the synthesis and secretion of GnRH, any alteration in its synthesis or secretion has resulted in menstrual abnormalities.[70,184] Amenorrhea may follow the discontinuation of contraceptive steroids, so-called *post-pill amenorrhea.* Contraceptive steroids have a suppressive effect on the pituitary that sometimes persists after medication has been discontinued. In most women, menses resumes within 6 months after discontinuation of oral contraceptives.[70]

Tests for the Evaluation of Amenorrhea

Evaluation of Primary Amenorrhea

When puberty is delayed in a girl, measurement of serum gonadotropins is useful for diagnostic purposes. Low concentrations may indicate pituitary failure, whereas concentrations elevated into the postmenopausal interval indicate definite gonadal failure.[46,268,375] In the latter case, chromosome studies are indicated. In the former case, pituitary function testing and radiography may be helpful. Patients

with short stature without Turner's syndrome but with primary amenorrhea may have multiple deficiencies of pituitary hormone secretion. In these patients, a craniopharyngioma or pituitary tumor should be suspected.

The diagnosis of *17α-hydroxylase deficiency* is made when (1) serum progesterone is greater than 3 ng/mL; (2) 17α-hydroxyprogesterone is <0.2 ng/mL; (3) aldosterone is low; and (4) an elevated 11-deoxycorticosterone concentration exists. Plasma concentrations of 11-deoxycortisol, testosterone, estradiol, and DHEA-S are also low. This diagnosis is confirmed with an *ACTH stimulation test.* After baseline progesterone and 17α-hydroxyprogesterone are measured, 0.25 mg of ACTH is administered. Diagnosis is made if serum concentrations of progesterone are significantly elevated and 17α-hydroxyprogesterone concentrations are unchanged at 60 minutes after ACTH administration.[69,250]

Many causes of secondary amenorrhea have also caused primary dysfunction. These disorders are discussed in the following section. Often, delayed puberty is not caused by specific organic disease, but is simply an unusual outcome of the spectrum of maturation.

Evaluation of Secondary Amenorrhea

In the evaluation of women with amenorrhea, a careful history and physical examination in those who are otherwise normal usually leads to determination of the correct cause. The history should define the complete description of the menstrual patterns; the presence or absence of galactorrhea; hot flashes; symptoms of hypothyroidism; hirsutism; prior surgery of the abdomen, pelvis, or uterus; trauma; medications; nutritional history; patterns of exercise; previous contraceptive use; changes in weight; stress; and chronic diseases. The physical examination should determine the visual fields, thyroid size and function, cushingoid appearance, galactorrhea, hirsutism, abdominal masses, pelvic masses, clitoral enlargement, and evidence of malnutrition. Serum or urine β-hCG should be measured to rule out pregnancy. Because both hypothyroidism and hyperprolactinemia can cause amenorrhea, they are easily excluded by measuring serum thyroid-stimulating hormone and prolactin concentrations.

A 24-hour urine sample for cortisol measurement or an overnight dexamethasone suppression test is performed in those patients suspected of having Cushing's syndrome (see Chapter 51). Based on the preliminary assessment, computed tomography of the sella should be performed in patients with evidence of pituitary or hypothalamic disease. A GnRH stimulation test with measurement of LH and FSH concentrations in those patients with gonadotropin deficiency assists in differentiating hypothalamic disease from pituitary disease. For diagnosis of PCOS, see the later section on the laboratory evaluation of hirsutism/virilization.

Progesterone Challenge

When the cause of amenorrhea is unclear after the initial assessment, relative estrogen status should be determined. Serum estradiol is measured or a *progesterone challenge* performed.[46,375] Women with an estrogen-primed uterus have withdrawal vaginal bleeding after treatment with oral progestin (medroxyprogesterone acetate; Provera), 30 mg daily for 3 days, or 10 mg daily for 5 to 10 days, or 100 to 200 mg of progesterone in oil given intramuscularly. If estrogen concentrations are adequate, and the outflow tract is intact, menstrual bleeding should occur within a week of treatment. In patients with withdrawal bleeding, the plasma estradiol concentration is usually >40 pg/mL.[46,70] Measurement of serum estradiol can be made instead of the progesterone challenge, but is not preferred because estrogen concentrations fluctuate throughout the day, and withdrawal bleeding is an indication of a normal outflow tract.

If bleeding fails to occur after progestin challenge, then additional laboratory tests are indicated. LH and FSH should be measured to localize the problem to the follicle, pituitary, or hypothalamus. High gonadotropin concentrations and low estrogen indicate the ovarian follicle is not responding to the gonadotropin stimulation. A single measurement of LH or FSH >50 mIU/mL is a reliable indicator of ovarian failure. Because of the association of POF with thyroid, parathyroid, or adrenal insufficiency secondary to autoimmune disease, it has been suggested that patients younger than age 35 should be screened for thyroid antibodies.[70] The differential diagnosis for evaluation of amenorrhea is listed in Table 53-2. As indicated by the clinical presentation, special additional testing may be required.

If the patient demonstrates withdrawal bleeding after the progesterone challenge test, this indicates that the ovaries are producing sufficient estrogen to cause endometrial proliferation and there is no anatomical obstruction. Most of these women have a history of oral contraceptive use, stress, weight loss, or excessive exercise.

Laboratory Evaluation of Hirsutism/Virilization

The two most important screening tests used in the evaluation of women for hirsutism and virilization are the measurements of serum total or free testosterone and DHEA-S.[46,280] Elevation of DHEA-S concentrations suggests an adrenal origin of androgens, whereas elevations in testosterone suggest either an adrenal or ovarian source. Unless the history is suspect, neoplastic disease is unlikely if the serum testosterone concentration is <2 ng/mL, the DHEA-S concentration is <700 μg/dL, or the 17-KS concentrations are <30 mg/day.[46,116,287] Regardless of the source of the excess androgen production, the androstanediol glucuronide concentration is elevated in more than 90% of women with hirsutism, because it is a marker of excessive DHT production in skin. Because concentrations of SHBG can be decreased in hirsute women, there has been some debate over whether total testosterone or bioavailable testosterone (free and weakly bound testosterone) is more clinically informative in diagnosing hirsutism. The reader is directed to a review by Wheeler that discusses many of these issues.[357]

TABLE 53-2 Differential Diagnosis of Amenorrhea

Causes	FSH	LH	Estrogen (E_2)	Uterine Bleeding After Progesterone
Hypothalamic				
CNS—hypothalamic dysfunction				
Idiopathic	N	N	N	+
Secondary to medications	N	N	N	+
Secondary to stress	N	N	N	+
CNS—hypothalamic dysfunction or failure due to exercise	↓ or N	↓ or N	↓ or N	±

FSH, Follicle-stimulating hormone; *LH*, luteinizing hormone; *CNS*, central nervous system; *N*, value within normal reference interval; ↓, value below normal reference interval; ↑, value above normal reference interval; (↑, >25 mIU/mL, less than menopausal level; ±, positive or negative bleeding response to progesterone).

Patients with PCOS usually have estradiol concentrations >40 pg/mL and therefore exhibit a positive progesterone stimulation test. The diagnosis of PCOS can be confirmed with laboratory determinations of serum testosterone, DHEA-S, LH, and FSH. LH concentrations are frequently elevated, and FSH concentrations are disproportionately normal or low. It has been suggested that a ratio of LH to FSH >2.5 indicates the presence of PCOS.[46,287] The total testosterone concentration is modestly elevated in 40% to 60% of patients.[46,287] In women with normal testosterone concentrations, free testosterone is usually elevated.[287] Concentrations of DHEA-S are usually normal or slightly elevated.

Morning plasma 17α-hydroxyprogesterone concentrations are measured to evaluate *nonclassical* or *late-onset*

21-hydroxylase deficiency (NCAH, see Chapter 51). A concentration <200 ng/dL (<6.1 nmol/L) excludes this diagnosis, and a concentration >1500 ng/dL (>30 nmol/L) in nonpregnant women is confirmatory. When basal concentrations of between 200 and 1500 ng/dL are found, an ACTH stimulation test should be performed. NCAH typically has a 17α-hydroxyprogesterone concentration of >1500 ng/dL, and classical CAH has a response more than 2000 ng/dL.[227,275,280] Patients with attenuated forms of CAH usually have normal concentrations of FSH and LH. About one half have elevated testosterone and androstenedione concentrations.[376] Most of these patients also have increased concentrations of DHEA-S, and more than 90% have supranormal concentrations of androstanediol glucuronide.[223,253]

Menopause

Menopause is defined as the permanent cessation of menstruation resulting from loss of ovarian follicular activity.[273] The ovaries fail to produce adequate amounts of estrogen and inhibin and, as a result, gonadotropin production increases in a continued attempt to stimulate the ovary (see Figure 53-14). The mean age of menopause in the United States is 51, but this age varies considerably.[35,46,129,168] Ovarian failure may occur at any age, but menopause before age 40 is considered premature.[70]

Hormonal changes begin about 5 years before the actual menopause, as the response of the ovary to gonadotropins begins to decrease, and menstrual cycles become increasingly irregular.[129,168,314] The term "perimenopausal" refers to the time interval from the onset of these menstrual irregularities to menopause itself. This transition phase can last from 2 to 8 years.[129,314] At this time, FSH concentrations increase and estradiol concentrations decrease, whereas LH and progesterone concentrations remain unchanged, indicating that the menstrual cycles are ovulatory. As estrogen continues to decline, there is an associated decrease in prolactin concentrations. The decrease in estrogen concentrations gives rise to vasomotor instability and "hot flashes."

After menopause, the ovary continues to produce androgens, particularly testosterone and androstenedione, as a result of increased LH concentrations. In addition, the adrenal gland continues to secrete androgens. The resulting decrease in the estrogen/androgen ratio is the cause of hirsutism often seen in postmenopausal women.[168] Prolonged estrogen deficiency results in increased resorption and bone remodeling, leading to accelerated bone loss and osteoporosis in postmenopausal women. Estrogen replacement therapy reduces bone loss and has been reported to reduce fracture risk by half.[129,168] The issue of hormone replacement treatment for menopausal symptoms, osteoporosis, various cardiac problems, and other disorders has received a great deal of attention. Data from several studies concerning the benefits and risks have changed ideas about indications and contraindications.[72,123,294] There is no single, reliable hormonal marker of menopause status for a given woman. Physicians should diagnose menopausal status based on menstrual history and age without relying on laboratory test results.[20,40]

It is important to note that with the advent of highly sensitive immunoassays for the measurement of serum and urine β-hCG concentrations, it has been occasionally observed that postmenopausal women have slightly elevated β-hCG concentrations (typically >5 but <25 IU/L).[5,14,28,193] These results may cause confusion when the concentrations are above the detection limit defined for a positive pregnancy test. Although this phenomenon is not associated with pregnancy, these results are not false positives as they are routinely confirmed by alternate methods.

INFERTILITY

Ninety percent of healthy couples practicing unprotected intercourse can expect to conceive within 1 year, and 95% will be successful within 2 years. *Infertility* is defined as the inability to conceive after 1 year of unprotected intercourse.[16,46,347] It is estimated that 25% of couples will experience an episode of infertility during their reproductive life.[171] Primary infertility refers to couples or patients who have had no previous successful pregnancies. Secondary infertility encompasses patients who have previously conceived, but are currently unable to conceive. Both types of infertility generally share common causes.

Infertility problems often arise as a result of hormonal dysfunction of the hypothalamic-pituitary-gonadal axis. Measurement of peptide and steroid hormones in the serum is therefore an essential aspect of the evaluation of infertility. This section focuses on the hormonal and biochemical aspects of evaluating infertility.

Male Infertility

Causative Factors

It has been reported that ~50% of infertility problems are male in origin.[109,312] However, male infertility often goes undetected, because low sperm count or abnormal sperm motility, combined with normal female reproductive function, merely results in delayed conception. Most infertile men (80%) will not have a definable cause and are said to have so-called "idiopathic impaired sperm function."[321] In about 20% of cases, a cause can be determined.[321] A study at Monash University Infertility Clinic in Australia indicated that primary testicular failure accounted for 11% of male patients seen; 8.5% had genital tract obstruction, 0.5% had hypothalamic-pituitary disease, and less than 1% had coital disorders or abnormal sperm.[13,321] A list of the most common male infertility factors is given in Box 53-4.

Many of the endocrine disorders that result in male infertility have been discussed earlier in this chapter in the section on male reproductive abnormalities. Testosterone is essential for normal sperm development. Therefore, any disorder that results in hypogonadism (and hence low testosterone concentrations) results in infertility. Among the causes are both hypogonadotropic and hypergonadotropic hypogo-

BOX 53-4 Male Infertility Factors

Endocrine Disorders
- Hypothalamic dysfunction (Kallmann's syndrome)
- Pituitary failure (tumor, radiation, surgery)
- Hyperprolactinemia (drug, tumor)
- Exogenous androgens
- Thyroid disorders
- Adrenal hyperplasia
- Testicular failure

Anatomic
- Congenital absence of vas deferens
- Obstructed vas deferens
- Congenital abnormalities of ejaculatory system
- Varicocele
- Retrograde ejaculation

Abnormal Spermatogenesis
- Unexplained azoospermia
- Chromosomal abnormalities
- Mumps orchitis
- Cryptorchidism
- Chemical or radiation exposure

Abnormal Motility
- Absent cilia (Kartagener's syndrome)
- Antibody formation

Psychosocial
- Unexplained impotence
- Decreased libido

Modified from Morell V. Basic infertility assessment. Primary Care 1997;24:195-204.

nadism. The most common cause of hypothalamic hypogonadism is *congenital idiopathic hypogonadotropic hypogonadism* (IHH) or its variant, Kallmann's syndrome (see earlier section on male reproductive abnormalities).[242] An adult-onset form of IHH has been recognized as a potentially treatable form of male infertility.[235] Ten men with postpubertal development of sexual dysfunction, low serum testosterone, and a pulsatile secretion of LH were compared with 24 cases of classic GnRH deficiency and 29 normal control subjects. The decreased serum GnRH concentrations in the adult-onset group were similar to those in the classic cases of IHH. Men with adult-onset IHH had larger mean testicular volumes and serum testosterone concentrations (78 ± 34 versus 49 ± 20 ng/dL) than classic cases of IHH. Treatment with GnRH successfully reversed hypogonadism and restored fertility in each of five men who accepted therapy.[235]

Pituitary insufficiency or failure can also cause infertility and is primarily caused by adenomas, but can also be caused by trauma, infiltration, metastases, or hemochromatosis. Hyperprolactinemia is a cause of secondary testicular dysfunction.[130] Prolactin excess likely causes hypogonadism by impairing GnRH release. It also leads to underandrogenization and impotence (see earlier section on impotence). Pituitary adenomas and drugs such as anxiolytics, antihypertensives, serotonergics, and histamine H_2 receptor antagonists will increase serum prolactin.[372]

Other endocrine causes of infertility include exogenous androgens, thyroid disorders, adrenal hyperplasia, and testicular failure. Gynecomastia or obesity in the infertile male may signify elevated concentrations of estrogen and possibly testicular feminization syndrome (see earlier section on male reproductive abnormalities).[109]

Antibodies to sperm surface antigens are a well-documented cause of infertility. They can decrease motility, cause agglutination, and be responsible for failure of sperm to penetrate human ova.[338] Antibodies arise from autoimmune processes that can be initiated by infection, trauma, obstruction, cryptorchidism, and cancer.[109,243] Immunosuppressive therapy has shown little to no benefit.

Among the other causes of male infertility are anatomical abnormalities, abnormal spermatogenesis, abnormal motility, and psychosocial causes. A list of drugs that can affect male reproductive function is given in Table 53-3.

Evaluation of Male Infertility

An initial evaluation of male infertility should include a detailed history and physical examination with special emphasis on the reproductive organs for evidence of proper androgenization. The history must include prescribed medications, recreational and performance-enhancing drug and alcohol use, systemic illnesses, and potential toxin exposure. A sexual history should include sexual technique and frequency of intercourse. Issues of potency must be distinguished from those of infertility or subfertility.

The laboratory evaluation of male infertility is separated into three main components: (1) the semen analysis, (2) endocrine parameters, and (3) immunological parameters. A basic approach to the diagnosis of male factor infertility is shown in Figure 53-15.

Evaluation of Semen

Semen Analysis. The semen analysis measures ejaculate volume, pH, sperm count, motility, and forward progression. Semen should be analyzed within 1 hour after collection. Although the semen analysis is not a test for infertility, it is considered the most important laboratory test in the evaluation of male fertility. Controversy exists as to what constitutes a "normal" semen profile. With the exception of the *azoospermic* male (defined as no sperm in the ejaculate), the lines between fertility and infertility are blurred, and are intimately associated with the status of the female partner's reproductive function. However, clinical studies of infertile men and World Health Organization (WHO) guidelines have helped establish limits of adequacy (Table 53-4).[109,362]

TABLE 53-3 Drugs and Chemicals Affecting Male Reproductive Function

Drug/Chemical	Effect
Alcohol	Depression of testicular production and increase in peripheral metabolism of testosterone, independent of liver disease
Amebicides	Toxic to testes in animals and humans
Antihypertensives	Depression of libido and potency
Arsenic	Replacement of phosphorus in DNA synthesis
Aspirin	Inhibition of prostaglandins in seminal fluid
Busulfan	Radiomimetic
Chlorambucil	Azoospermia
Colchicine	Arrests cell division in metaphase
Cyclophosphamide	Depression of spermatogenesis
Diethylstilbestrol (in utero)	Small testes, poor semen quality
Lead poisoning	Oligospermia, poor motility, abnormal sperm forms
Marijuana	Depression of sperm count and testosterone
Medroxyprogesterone	Male pill, reversible
Methotrexate	Mutagenic
Monoamine oxidase inhibitors	Decreased sperm count
Nicotine	Depression of sperm motility and density
Nitrofurantoin	Interference with carbohydrate metabolism in germinal epithelium leading to arrest at spermatocyte stage (dose related, reversible)
Phenytoin sodium	Depression of follicle-stimulating hormone levels
Spironolactone	Decreased testosterone concentrations
Sulfasalazine	Depression of sperm counts, reversible
Testosterone	Germinal atrophy by suppressing luteinizing hormone and decreasing intratesticular testosterone
Triethylenemelamine	Radiomimetic

From Caldemone AA. Evaluation of the infertile or subfertile male. Urol Clin North Am 1981;8:17.

Sperm Function. Functional tests have yet been established that can unequivocally predict the fertilizing capacity of spermatozoa. However, detailed methods describing the analysis of sperm function exist in the current literature.[109] These methods attempt to measure the functions of sperm necessary for fertilization. For a sperm to be successful, it must be able to (1) reach the ova through directed motility, (2) undergo capacitation, (3) fuse with the oocyte membrane, and (4) be incorporated into the oocyte cytoplasm.[109] The postcoital test (as described in the later section on evaluation of female infertility) is the most widely used measure of sperm adequacy. The WHO has accepted and offered guidelines for the postcoital test and the sperm-mucus penetration test.[362] The sperm-mucus penetration test evaluates the ability of sperm to travel through a vaginal mucus sample obtained from either the female partner or a donor. This test is no longer performed on a routine basis and the reader is referred to an earlier edition of this chapter for a complete description of this procedure.[133] Other tests such as the hypo-osmotic swelling test, hamster oocyte penetration test, and acrosome reaction test are still considered experimental and have not gained universal acceptance.[243]

Evaluation of Obstruction. Analysis of specific semen parameters has proven useful in the evaluation of male reproductive tract obstruction. Testosterone produced after administration of hCG causes the seminal vesicles, epididymis, and prostate to increase the volume of ejaculate. An appropriate increase in serum testosterone without change in the ejaculate volume may indicate mechanical blockage. Absence or decrease in specific biochemical markers such as acid phosphatase and citric acid (from prostate), fructose, and prostaglandins (from seminal vesicles) aids in determining the location of blockage.[121] Low seminal glucosidase concentrations, in the presence of testes of normal size and consistency, normal semen volume, and normal serum FSH, have also been used as an indication of obstruction (usually in the epididymis) or congenital bilateral absence of the vas deferens (a condition associated with mutations of the cystic fibrosis gene).[105]

Evaluation of Endocrine Parameters

Serum testosterone should be measured especially when the patient history or physical examination suggests deficient development of secondary sex characteristics. Patients with borderline or suppressed testosterone concentrations are

TABLE 53-4 Normal Seminal Fluid Values

Parameter	Value
Ejaculate volume	>2 mL*
Sperm density	>20 million/mL*
Total sperm count	>40 million/ejaculate*
Motility	>50% with forward progression or >25% with rapid progression within 60 min of ejaculation*
Morphology	>30% normal*
pH	7.2-8.0*
Color	Gray-white-yellow
Liquefaction	Within 40 min
Fructose	>1200 µg/mL
Acid phosphatase	100-300 µg/mL
Citric acid	>3 mg/mL
Inositol	>1 mg/mL
Zinc	>75 µg/mL
Magnesium	>70 µg/mL
Prostaglandins ($PGE_1 + PGE_2$)	30-200 µg/mL
Glycerylphosphorylcholine	>650 µg/mL
Carnitine	>250 µg/mL
Glucosidase	>20 mU per ejaculate

*Values from World Health Organization: laboratory manual for the examination of human semen and semen-cervical mucus penetration. 3rd ed. Cambridge, UK: Cambridge University Press, 1992.

evaluated with an *hCG stimulation test.* With this test, an injection of 5000 IU hCG is administered intramuscularly following collection of a basal, early morning testosterone sample. Serum testosterone is measured 72 hours later. Hypogonadal men show a depressed testosterone rise in response to this challenge. A doubling of testosterone concentration over baseline is consistent with normal Leydig cell function. Failure to increase testosterone >150 ng/dL indicates primary hypogonadism.[170]

Hypergonadotropic Hypogonadism. Follicle-stimulating hormone measurement is indicated in men with sperm counts of less than 5 to 10 million/mL. Elevated concentrations of FSH indicate Sertoli cell dysfunction and, in azoospermic men, primary germinal cell failure, Sertoli-cell–only syndrome, or genetic conditions such as Klinefelter's syndrome.[122] Elevated FSH (>120 mIU/mL) in the setting of decreased testosterone (<200 ng/dL) and oligospermia indicate primary testicular failure or "andropause" (see previous section on andropause).

Hypogonadotropic Hypogonadism. Decreased concentrations of testosterone (<200 ng/dL) and decreased concentrations of FSH (<10 mIU/mL) are suggestive of hypogonadotropic hypogonadism. Administering GnRH may help to distinguish between gonadal insufficiency caused by pituitary versus hypothalamic failure. Because the pituitary is sensitive to sex steroids for appropriate gonadotropin secretion, patients with long-standing hypogonadism should be given exogenous testosterone for 1 week before the GnRH stimulation test. One approach to this test involves the intravenous injection of 100 µg of GnRH with measurement of FSH and LH concentrations at 0, 30, 60, 120, and 180 minutes after injection. Results of the GnRH test are classified as follows. An increase in serum gonadotropins ≥10 mIU/mL over baseline is normal. If there is little to no increase in gonadotropins, pituitary disease is likely. Patients with hypothalamic disease will demonstrate a delayed but significant increase ≥7 mIU/mL within 180 minutes.[170]

Evaluation of Immunological Parameters

The method of measurement of antisperm antibodies is identical for male or female infertility evaluation. Agglutination, immobilization, enzyme-linked immunosorbent assays, radioimmunoassays (RIA), and immunofluorescent assays are available.[47,140] The immunobead technique is the most widely used and is reported to have excellent clinical sensitivity (97.5%) and acceptable clinical specificity (66%).[47] In this technique, a polyacrylamide bead is coated with a rabbit antihuman antibody. This binds to antibodies that are either already present on human sperm, or present after incubation of sperm with the appropriate fluid (cervical mucus or serum). Beads that bind sperm are microscopically detected. This technique allows determination of percentage of human sperm bound, the immunoglobulin isotype, and the location of antibody binding (head, midpiece, or tail).[38,47] The practice of testing for antisperm antibodies is not recommended.[365] Although antisperm antibodies are associated with infertility, the concentration at which these decrease fertility is unknown.

Female Infertility

Causative Factors

Factors that contribute to female infertility are shown in Box 53-5. Ovulatory disorders (including ovarian and hormonal causes) account for approximately 30%, pelvic factors (including tubal, cervical, and uterine disease) account for approximately 50%, and immunological factors are implicated in approximately 5% of infertility cases.[46] This section focuses primarily on the ovulatory and immunological factors, where the laboratory plays an important role.

Ovulatory Factors

Ovulatory dysfunction manifests itself in the presence or absence of normal menses, making it difficult to diagnose. Metabolic diseases of many kinds can effect ovulatory function, including ones that result in androgen excess. PCOS, which results in androgen excess, is the most common cause of anovulation and has been discussed in detail earlier in the chapter. In women with hirsutism, CAH should be considered. A 21-hydroxylase deficiency or 3-β-hydroxysteroid deficiency may be present in up to 26% of cases.[254] Ovulatory dysfunction can also be secondary to liver or thyroid disorders.

As with male infertility, hypogonadism (hypergonadotropic or hypogonadotropic) also results in female infertility. Causes of hypergonadotropic hypogonadism include POF, gonadal dysgenesis, resistant ovary syndrome, menopause, and luteal phase deficiency. Causes of hypogonadotropic hypogonadism include pituitary or hypothalamic insufficiency and hyperprolactinemia. Many of these pathological states have been discussed in the earlier section on irregular menses.

Ovulation with inadequate luteinization and reduced progesterone secretion during the luteal phase has been termed *luteal phase deficiency*. The contribution of luteal insufficiency to infertility is controversial. It is manifested by a short luteal phase, in which the interval between LH peak and the onset of menses is ≥10 days, or a normal length luteal phase with reduced progesterone secretion.[46] An inadequate luteal phase and deficit of progesterone lead to poor proliferation of the endometrium and therefore an unsuitable environment for the early embryo.[46,376] Luteal dysfunction is believed to cause infertility in 5% of infertile women. It can be found periodically in 30% of women, and is not considered to contribute to infertility unless diagnosed twice in separate cycles.[347]

BOX 53-5 Female Infertility Factors

Ovarian or Hormonal Factors
- Metabolic disease
  - Thyroid
  - Liver
  - Obesity
  - Androgen excess
  - Polycystic ovarian syndrome
- Hypergonadotropic hypogonadism
  - Menopause
  - Luteal phase deficiency
  - Gonadal dysgenesis
  - Premature ovarian failure (autoimmune, cytotoxic chemotherapy, tumor)
  - Resistant ovary syndrome
- Hypogonadotropic hypogonadism
  - Hyperprolactinemia (tumor, drugs)
  - Hypothalamic insufficiency (Kallmann's syndrome)
  - Pituitary insufficiency (tumor, necrosis, thrombosis, stress, exercise, anorexia)

Tubal Factors
- Occlusion or scarring
- Salpingitis isthmica nodosa
- Infectious salpingitis

Cervical Factors
- Stenosis
- Inflammation or infection
- Abnormal mucus viscosity

Uterine Factors
- Leiomyomata
- Congenital malformation
- Adhesions
- Endometritis or abnormal endometrium

Psychosocial Factors
- Decreased libido
- Anorgasmia

Iatrogenic

Immunological (Antisperm Antibodies)

Modified from Morell V. Basic infertility assessment. Primary Care 1997;24:195-204.

Immunological Factors

Antisperm antibodies contribute to female infertility and may be present in female serum, in cervical mucus, or in seminal fluid. Their role in female infertility remains contentious. Some cases of infertility, especially when associated with an abnormal postcoital test, are found in the presence of a high percentage of sperm-binding antibodies.[38] The percentage of total binding and the region of binding (head, midpiece, or tail) appear to play a role in infertility and specifically in the ability of the sperm to bind the ovum in vitro.[38] However, one prospective study of 235 infertile couples examined pregnancy rates over time and found no correlation of serum antisperm antibodies between couples who achieved pregnancy and those who did not.[101] Cervical mucus and semen antisperm antibodies were not measured in this study. Methods for antisperm antibody measurement are described in the earlier section on evaluation of male infertility.

Evaluation of Female Infertility

The initial evaluation of female infertility should include a detailed history and physical examination, including a Papanicolaou cervical and vaginal smear with appropriate cervical and endocervical cultures, a search for tubal patency and endometriosis or adhesions, and assessment of ovulation and adequate luteal function.[160,171] After obvious treatable abnormalities have been excluded, a menstrual history indicates further endocrine evaluation and a postcoital test helps to determine coital sufficiency (Figure 53-16; see also earlier section on irregular menses).

Postcoital Test

The postcoital test is a quick assessment of multiple factors affecting fertility; however, opinions vary regarding its clinical utility. The test is scheduled around the time of the LH surge. A sterile speculum examination is performed 9 to 24 hours (based on WHO guidelines) after intercourse. A sample of endocervical mucus is aspirated and placed onto a glass slide with two coverslips. Mucus with adequate estrogen stimulation appears clear and thin and forms a thread 6 cm or greater in length when the coverslips are separated from the slide. This represents a positive "spinnbarkeit," which is defined as the formation of a thread by mucus from the cervix uteri when spread onto a glass slide and drawn out by a cover glass; the time at which it can be drawn to the maximum length usually precedes or coincides with the time of ovulation.[96] When examined under the microscope, mucus air dried under the second coverslip forms a fernlike pattern when adequate estrogen is present. Before the mucus has dried, greater than 20 motile sperm per high-power field should be visualized (WHO recommended cutoff).[246] A normal test result suggests coital sufficiency, probable ovulation, "nonhostile" cervical mucus, and a normal male fertility test.[347] Predictive values vary from nearly 50% chance of conception within 1 year with an optimal test to 15% chance of conception if the test is abnormal.[102]

Evaluation of Ovulation

Current laboratory tests do not confirm ovum release. However, the measurement of midluteal plasma progesterone does indicate that a corpus luteum was formed. Other methods, such as basal body temperature and evaluation of LH surge, have also been used to detect or predict ovulation.

Progesterone Measurement. Serum progesterone measurement is the primary assay used for the evaluation of ovulation.[171,297] It is important to note that an increase in the progesterone concentration indicates that a corpus luteum has been formed, but cannot confirm that the egg was actually released. Beginning immediately after ovulation, serum progesterone concentrations rise, and peak within 5 to 9 days during the midluteal phase (days 21 to 23).[297] If ovulation does not occur, the corpus luteum fails to form and the expected cyclical rise in progesterone concentration is subnormal. If pregnancy occurs, hCG stimulates the corpus luteum and progesterone production continues to rise. Midluteal progesterone concentrations of >10 ng/mL indicate normal ovulation; concentrations <10 ng/mL suggest anovulation, inadequate luteal phase progesterone production, or inappropriate timing of sample collection.[365]

Basal Body Temperature. Basal body temperature charts have long been accepted as simple and cost-effective indicators of ovulation. Ovulation is associated with a rapid rise in body temperature, by 0.5 °F, which persists through the luteal phase. The rise in temperature is due to the increased progesterone concentration. However, like progesterone, the rise in body temperature is evident only retrospectively and therefore does not predict imminent ovulation in a way helpful for timing intercourse.

Measurement of the Luteinizing Hormone Surge. Luteinizing hormone appears in the urine just after the serum LH surge and 24 to 36 hours before ovulation. Measurement of LH does not confirm the presence of ovulation or provide insight as to the etiology of anovulation, but rather indicates when ovulation should occur and can provide a guide with which to time intercourse. Methods for laboratory measurement of LH are given in Chapter 51.

Monoclonal technology has led to the use of *home LH kits* that not only provide accurate information as to the timing of ovulation but may reduce stress and costs associated with infertility programs because these tests are performed at home and are comparatively inexpensive.[191] Most home ovulation kits consist of a "dipstick" that uses a two-site, double monoclonal enzyme-linked immunoassay. Urine is applied to the test pad and capillary action draws the fluid across the pad. LH in the urine is first bound to an anti-LH antibody that is coupled to an enzyme conjugate, or colloidal gold. The LH-antibody complex then migrates to a region coated with a second anti-LH antibody. Once bound to this site, the substrate-enzyme reaction or colloidal gold complexes result in a color change that is proportional to the amount of LH present. A reference region is provided. A test result that matches or is darker in color than the reference region is considered a positive result, indicating that the LH surge is occurring. The tests effectively predict ovulation in 70% of women.[103] In some studies, these tests are said to be more reliable than laboratory plasma analysis, and the results are easily read by patients.[66,285] In one study of 26 normal women, home LH kits had a 92% positive predictive value for ovulation to occur within 48 hours of a positive urine LH screen.[226]

Evaluation of Endocrine Parameters

Hypergonadotropic Hypogonadism. Primary ovarian failure is indicated by repeatedly elevated basal FSH concentrations (>30 IU/L) or a single elevation of >40 IU/L. These patients are hypoestrogenic (estradiol <20 IU/L)[297] and do not respond to a progestin challenge (see earlier section on evaluation of secondary amenorrhea). Basal serum FSH can be used as an indicator of relative ovarian age. Figure 53-17 shows the relationship between rising serum FSH and the reduced rate of successful pregnancy. A precipitous drop occurs at concentrations >20 IU/L.

Luteal phase deficiency is diagnosed when the time between ovulation and menses is 10 days or less. The most specific diagnostic information may be gained from an endometrial biopsy obtained on day 26 of a 28-day cycle.[354] If peak progesterone concentrations are repetitively below 10 ng/mL, the diagnosis of luteal phase deficiency does not require an endometrial biopsy. Decreased progesterone production is presumed to be responsible, but this may follow insufficient follicular phase FSH secretion, abnormal LH surge, or other endocrine abnormalities.[313] Some studies show luteal phase deficiency to be no more prevalent in infertile women than in normal women.[309,353] Other studies have shown an association with an increased risk of infertility, ectopic pregnancy, and spontaneous abortion.[21,139] Luteal phase dysfunction may also be secondary to excess androgen production, which suppresses follicle development. Prolactin excess may also contribute to the development of this disorder.[320]

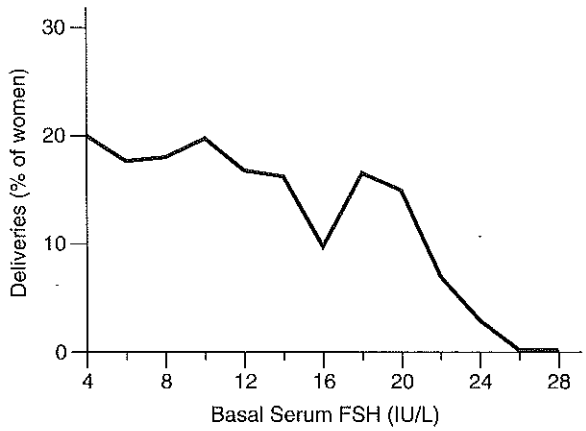

Figure 53-17 The relationship between increasing follicle-stimulating hormone (FSH) concentrations and decreased percentage of successful pregnancies. *(From Jones H, Toner JP. The infertile couple. N Engl J Med 1993;329:1710-5. Copyright © 1993 Massachusetts Medical Society. All rights reserved.)*

Hypogonadotropic Hypogonadism. In hypogonadotropic hypogonadism, serum estradiol concentrations are <40 pg/mL (110 pmol/L) and therefore there is no withdrawal bleeding with a progestin challenge.[284] Decreased LH (<10 IU/L) and decreased FSH (<10 IU/L) are also present.[297] Hyperprolactinemia also causes hypergonadotropic hypogonadic infertility. The upper limit of normal plasma prolactin in an amenorrheic, hypoestrogenic, nonpregnant woman is 400 to 500 mIU/mL (20 to 25 ng/mL). If estrogen status is normal, maximum prolactin concentrations vary from 600 to 800 mIU/mL (30 to 40 ng/mL).[198] Thyroid-stimulating hormone should be measured to exclude hypothyroidism. Prolactin concentrations can be elevated in patients with PCOS and those taking medications such as antidepressants, cimetidine, and methyldopa. Radiographic imaging of the pituitary is indicated to rule out pituitary adenomas or empty sella syndrome.

Assessing Ovarian Reserve. Women in their mid to late 30s and early 40s with infertility constitute the largest portion of the total infertility population. These women are

also at an increased risk for pregnancy loss. This reflects a diminished ovarian reserve as a result of follicular depletion and a decline in oocyte quality. As women age, serum FSH concentrations in the early follicular phase begin to increase. It has been suggested that this is caused by a decline in the number of small follicles secreting inhibin B.

Basal serum FSH and estradiol measurements have been the screening test of choice for assessing ovarian reserve. The rise in basal FSH is an excellent indicator of ovarian aging. In general, day 3 FSH concentrations >20 to 25 IU/L are considered to be elevated and associated with poor reproductive outcome.[181] Concomitant measurement of serum estradiol adds to the predictive power of an isolated FSH determination. Basal estradiol concentrations >75 to 80 pg/mL are associated with poor outcome.[203]

Inhibin B is produced by the developing follicles, and concentrations peak during the follicular phase. Concentrations of inhibin B have been used in conjunction with serum FSH and estradiol to assess ovarian function. Because inhibin is produced by gonadal tissue, it is thought to be a more direct marker of gonadal activity and ovarian reserve than pituitary hormones. In addition, cycle day 3 inhibin B concentrations may demonstrate a decrease before day 3 FSH concentrations.[300]

Seifer and colleagues reported that women undergoing in vitro fertilization (IVF) with day 3 inhibin B concentration <45 pg/mL had a pregnancy rate of 7% and spontaneous abortion rate of 33% as compared with pregnancy rate of 26% and abortion rate of 3% in women with day 3 inhibin B concentrations of >45 pg/mL.[299] Women who have diminished ovarian reserve should be counseled regarding options such as oocyte donation or adoption.

Assisted Reproduction

Couples with a multitude of infertility problems, including unidentified causes and persistent infertility despite standard treatments, may benefit from assisted reproductive techniques. Standard initial therapy consists of ovulation induction and artificial insemination for at least 6 months before progressing to more expensive and exotic techniques.

The laboratory plays an important role in the process of ovulation induction. The principle involves administration of gonadotropins to stimulate follicular growth followed by hCG to stimulate ovulation. Clinical, laboratory, and ultrasound monitoring of the treatment cycle is necessary to (1) determine the dose and length of therapy, (2) determine when or whether to administer hCG, and (3) obtain an adequate ovulatory response while avoiding hyperstimulation.[298]

Assisted reproductive techniques involve procedures that deliver a concentrated sperm sample directly to the uterus (artificial insemination), or procedures that acquire fertile ova using laparoscopic or ultrasonographic techniques and assisting fertilization in the laboratory (in vitro fertilization) or in the fallopian tubes using either gamete intrafallopian transfer or zygote intrafallopian transfer.[232] In vitro fertilization then requires embryo transfer back into the uterus. Gamete intrafallopian transfer places unfertilized ova and sperm directly into the fallopian tube, whereas zygote intrafallopian transfer involves placing the fertilized zygote into the fallopian tube. The latest successful techniques include direct ovum fertilization using micropipette penetration of the zona pellucida and introduction of the sperm or direct intracytoplasmic injection of the sperm.[303] These procedures provide hope to even the azoospermic man for whom testicular aspiration may yield a few nonmotile sperm.

ANALYTICAL METHODOLOGY

Many methods are available for measuring reproductive hormones in body fluids. Methods for the reproductive protein hormones are discussed in Chapter 50. Methods for the reproductive steroid hormones are discussed in the following sections.

Measurement of Total Testosterone in Blood

Circulating testosterone comprises three different forms or pools: a non–protein-bound or "free" form, a weakly bound form, and a tightly bound form. The weakly bound form is associated with albumin and the tightly bound form with SHBG (also known as testosterone/estradiol-binding globulin). The term *total testosterone* refers to serum measurements of (1) free testosterone, (2) albumin-bound testosterone, and (3) SHBG-bound testosterone. Bioavailable testosterone includes circulating free testosterone and albumin-bound testosterone.[130] Testosterone bound to SHBG is not biologically active, whereas the free form is available for target cells. Albumin-bound testosterone is also available to target tissue, because testosterone can dissociate from the albumin carrier and rapidly diffuse into target cells.[130]

Methodology

Early methods for measuring serum or plasma testosterone using fluorometry, double-isotope derivative, electron-capture gas-liquid chromatography, and competitive protein binding assays have been largely replaced by immunoassays that use specific antisera.[179,208] A 2002 CAP survey from the College of American Pathologists (CAP) reports that enzyme (nonisotopic) immunoassays have replaced RIAs as the most widely used technique for measuring the concentration of circulating testosterone (both protein-bound and non–protein-bound forms).[64] Individual immunoassay methods differ mainly in the mode of sample preparation, in the quality of antisera used, and in the nature of the steroid-protein conjugate used to generate the antiserum.[165] Gas chromatography combined with mass spectrometry (GC-MS) remains the reference method for testosterone measurement and is often used to assess the bias of routine immunoassay methods.[95,108,110] It has been suggested that liquid chromatography-tandem mass spectrometry (LC-

MS/MS) may become the clinical method of choice for measuring low testosterone concentrations.[350A]

Direct (no extraction required) immunoassay methods have been reported for the determination of testosterone in serum or plasma.[161,179] The steroid must be displaced from its binding proteins (albumin and SHBG). The results of the assay depend on the effectiveness of the displacement. Methods used to release testosterone from the endogenous binding proteins include use of salicylates or surfactants, pH alterations, temperature changes, and competing steroids such as estrone or estradiol. Most of the direct immunological methods use antisera generated against a C_{19} testosterone-protein conjugate.[165] Several commercial assay kits for direct assay of testosterone are available. These kits are classified into two types: RIA and automated, nonisotopic immunoassay. Many single-step kits employ antibody-coated tubes or magnetic particles for added convenience, eliminating the need for centrifugation. Liquid- or solid-phase double-antibody methods have also been introduced.

Fully automated immunoassays incorporating analogs labeled with enzymes, and fluorescent- or chemiluminescent-signaling molecules have been described and are commercially available for routine use.[29,165,292,358] The advantages of the newer, nonisotopic immunoassay formats include (1) faster results, (2) smaller sample size, and (3) the elimination of radioactive reagents. For adult male patients, these assays have demonstrated good precision and recovery, and agreement with GC-MS–validated pools and established RIA methods.[110,292,358] However, there is some question regarding the utility of such assays for female and prepubertal subjects.[111,152,325,358,363] The testosterone is low in these subjects and measurements compare poorly with mass spectrometry methods.[325,350A,363] The accuracy of immunoassay combined with extraction is uncertain.[152]

The preferred tracer in commercially available RIA kits for labeled testosterone is ^{125}I. The size of the iodinated group and the site of linkage may greatly affect assay affinity and specificity. Some methods use solvent extraction or chromatography, or both, to remove interferences from other steroids and some drugs. These preliminary steps also permit concentration of the sample when low concentrations of testosterone are expected. Like automated assays, manual RIA assays perform better at higher concentrations, with questionable utility in female and prepubertal subjects.[27,95]

Direct assays for total testosterone may produce spuriously high results, especially at low concentrations. In particular, some samples collected from women give concentrations within the reference interval for men when direct assays are used, but yield concentrations within the normal reference interval for women if extraction methods are used.[111,165,358,359] Similar interferences have been reported in the direct measurement of testosterone in infants.[118] During the first 3 weeks postpartum, testosterone concentrations measured by a direct assay were 3.8-fold greater than those measured after purification. These differences were most prominent in the first week of life, although some persisted through the first 2 months. This lack of accuracy is serious and may result in misdiagnosis and inappropriate treatment. Overestimations of testosterone concentrations by some direct methods are thought to be caused by the presence of a water-soluble cross-reacting substance(s).[264] Alternatively, the presence of endogenous antibodies that recognize the labeled testosterone analogs may cause falsely elevated concentrations.[337]

The validity of assay results is best proved by tests for parallelism of the response curves for both calibrators and randomly selected samples from male and female subjects of various ages. In addition, comparison of extraction/chromatography immunoassays should be validated by comparison with mass spectrometry methods.[152] Direct immunoassays should not be used for female and prepubertal subjects, especially infants. These groups should be tested using an extraction immunoassay or an LC-MS/MS assay. It is important to note that both types of direct immunoassay demonstrate problems with functional sensitivity for low concentrations. Each lab should determine the low-end detection limit of their assay despite manufacturer claims.

Regardless of immunoassay type, almost all testosterone antisera show some degree of cross-reactivity with DHT (typically 3% to 5%), but show negligible cross-reactivity with other androgens. Assays that use antisera generated against the C-19 position give maximum analytical specificity with respect to endogenous steroids. However, cross-reactions with 19-norsteroids that are used in contraceptive preparations have caused a problem. In most clinical situations, estimation of testosterone without prior separation of DHT is permitted because plasma concentrations of DHT are only 10% to 20% of those for testosterone. Moreover, testosterone and DHT are the two most important androgens in the systemic circulation; even when a method measures the concentrations of both of them, clinically useful information about the total androgen load is obtained. However, if specific estimation of testosterone concentration is required, then chromatographic separation of testosterone and DHT before immunoassay is usually necessary to obtain consistently reliable results.[169]

Specimen Collection and Storage

Either serum or heparinized plasma is used to measure total or free testosterone. Testosterone is subject to a diurnal variation, reaching a peak concentration between 0400 hours and 0800 hours. Therefore, morning specimens are preferred. Specimens are stable for a week (men) or 3 days (women) refrigerated and for up to 1 year frozen at 20 °C.[85,163] No steroids, thyroid, ACTH, estradiol, or gonadotropin medications should be given for 48 hours before sample collection.[92,138] Most assays are standardized for serum or heparinized plasma. Other anticoagulants such as ethylenediaminetetraacetic acid (EDTA) may give different values. In certain RIA assays, presence of EDTA appears to cause a 10% decrease in total testosterone concentrations.[85]

TABLE 53-5 Reference Intervals for Total Testosterone in Serum

	ng/dL	nmol/L
Prepubertal Levels		
1-5 mo, Male	1-177	0.03-6.14
Female	1-5	0.03-0.17
6-11 mo, Male	2-7	0.07-0.24
Female	2-5	0.07-0.17
1-5 yr, Male	2-25	0.07-0.87
Female	2-10	0.07-0.35
6-9 yr, Male	3-30	0.10-1.04
Female	2-20	0.07-0.69
Pubertal Levels (Tanner Stage)		
1, Male	2-23	0.07-0.80
Female	2-10	0.07-0.35
2, Male	5-70	0.17-2.43
Female	5-30	0.17-1.04
3, Male	15-280	0.52-9.72
Female	10-30	0.35-1.04
4, Male	105-545	3.64-18.91
Female	15-40	0.52-1.39
5, Male	65-800	9.19-27.76
Female	10-40	0.35-1.39
Adult Levels		
Male	260-1000	9-34.72
Female	15-70 (higher at mid-cycle peak)	0.52-2.43

Reference Intervals

Reference intervals for total testosterone in serum are listed in Table 53-5.[261,336] Reference concentrations for total testosterone in other body fluids are listed in Chapter 56 and elsewhere.[336]

Comments

Estimation of SHBG in serum is sometimes very useful for interpreting blood concentrations of testosterone.[301] Procedures for measuring SHBG have been reviewed elsewhere.[281] Two types of assays are generally available: (1) binding assays, in which the quantity of a radiolabeled androgen bound to SHBG is measured; and (2) specific immunoassays for the SHBG protein. Commercial kits for SHBG determination are available. Serum concentrations measured using a solid-phase immunoenzymometric assay vary from 10 to 80 nmol/L in men and 20 to 130 nmol/L in nonpregnant women.[218] When measured using an RIA, SHBG concentrations vary from 6 to 44 nmol DHT bound per liter in men, and from 8 to 85 nmol DHT bound per liter in women.[261] Interference by SHBG has been reported to occur in a number of direct RIAs for testosterone[23,216]; the use of extraction techniques, however, abolishes the influence of SHBG.

Measurement of Free and Weakly Bound Testosterone in Blood

In cases in which SHBG concentrations are altered, such as in women, aging men, and illness, measurements of free or bioavailable testosterone are believed to be better reflections of androgen status. An excellent review of various methods used to measure this fraction of testosterone is available.[357]

Several methods are available for determining the concentrations of the free or bioavailable forms of testosterone in serum or plasma: (1) estimation of the free testosterone fraction by equilibrium dialysis or ultrafiltration; (2) estimation of the free hormone using a direct ("analog tracer") immunoassay; (3) estimation of the combined free and weakly bound ("bioavailable") testosterone fractions by selective precipitation of the tightly bound form; (4) calculation of androgen index using indices that reflect ratios of the testosterone pools; and (5) calculation of free and weakly bound testosterone concentrations by mathematical modeling.[308,346,357] The last approach uses mass action equations to calculate free and weakly bound testosterone concentrations from the concentrations of total testosterone, SHBG, and albumin, and from the association constants for the binding of testosterone to the two binding proteins.

Equilibrium Dialysis/Ultrafiltration

Only a small fraction (1% to 2%) of unconjugated testosterone exists freely (non–protein bound) in serum or plasma. None of the conventional assay methods, including RIA, is sufficiently sensitive to quantify the free steroid directly in a protein-free ultrafiltrate of plasma. Instead, the free steroid is estimated in plasma by adding a known amount of radiolabeled compound to the sample and allowing labeled and unlabeled compounds to reach equilibrium in their competition for the same binding sites on the proteins. Bound and free radiolabeled fractions are then separated and the ratio of free labeled to total labeled compound is determined. At equilibrium, this ratio is taken as a measure of the free testosterone fraction. An estimate of serum free testosterone can then be calculated by multiplying the free testosterone fraction by the total testosterone concentration.

Methodological Principle

In the equilibrium dialysis/ultrafiltration method for determining free testosterone in blood, a sample is first equilibrated with radioactive testosterone. Free steroid is then separated from bound steroid by filtration through an anisotropic, hydrophilic ultrafiltration membrane. The driving force for ultrafiltration is provided by centrifugation at 1000 to 2000 ×g. Filtrate containing free steroid collects in the filtrate cup, whereas protein-bound steroid remains above the filter. Radioactivity in the filtrate is a measure of

the free testosterone fraction. A detailed procedure for the equilibrium dialysis method is included in the previous edition of this chapter.[133]

Reference Intervals

Reference intervals for free testosterone and percent free testosterone in serum are listed in Table 53-6 and in Chapter 56.[261,336] These concentrations compare favorably with those obtained when using membrane ultrafiltration and gel filtration methods. Equilibrium dialysis is considered the reference method for determining free testosterone in serum.

Comments

Most problems with this procedure have involved tracer impurities and the separation of bound and free labeled fractions. Several separation techniques have been used, including equilibrium dialysis, membrane ultrafiltration, and steady-state gel filtration. Their deficiencies include a requirement for a large sample volume, the need for complicated correction of sample volume changes that occur during the separation, and difficulties of collecting and measuring radioactivity in numerous fractions of each sample. Equilibrium dialysis has been used most often in the past, but serious errors often arise from the sample dilution required by this method.[345] Symmetrical dialysis of undiluted samples is reported to be less susceptible to tracer contamination and dilution effects.[322] Ultrafiltration also appears to overcome these problems and to obviate errors caused by dilution.[142]

Direct Immunoassay

Several RIA procedures are commercially available for the direct estimation of free testosterone.[179,231,286,357,368] These assays use a labeled derivative (analog) of testosterone that, in theory, retains the ability to react with exogenous antitestosterone antibodies, but is restricted from interacting with testosterone-binding proteins in the serum sample. The analog method is claimed to have a significant advantage as a screening test for investigating androgen excess in women,[364] although others have found free androgen index to be a better indicator.[357]

The advantages of RIA analog methods include a small sample requirement, relatively rapid results, an easy procedure, and the option to measure free testosterone without having to measure total testosterone.[179,231,346,368] Thus the RIA analog assays are the most commonly used method for determining free testosterone. Although there is reportedly good correlation between the values obtained by RIA and equilibrium dialysis, the RIA assays are grossly inaccurate, underestimating free testosterone concentrations by many fold.[231,282,283,346] One study in females revealed that free testosterone concentrations obtained by two different analog assays were 15% to 35% and 25% to 30% of those obtained by ultrafiltration.[137] The calculated free testosterone is considered more reliable than the RIA method.

Selective Precipitation

Measurement of bioavailable testosterone has been estimated by selective precipitation of SHBG with ammonium sulfate. In this technique, aliquots of serum or plasma are first incubated with tritiated testosterone. Testosterone bound to SHBG is then precipitated with 50% ammonium sulfate. The samples are centrifuged, and aliquots of the supernatant containing the free and albumin-bound testosterone (also known as *non–SHBG-bound testosterone*) are counted. The percentage of tritiated label not bound to SHBG is subsequently multiplied by the total testosterone concentration to give the bioavailable testosterone.[357] The amount of bioavailable testosterone has also been measured directly, by RIA, in the supernatants of plasma after ammonium sulfate precipitation and solvent extraction.[75] An indirect method using a commercially available enzyme immunoassay has been described for measuring bioavailable testosterone.[71] Alternatively, the fraction of testosterone not bound to SHBG has also been estimated by a technique that involves saturating SHBG binding sites with 5α-DHT, the natural steroid bound with highest affinity by SHBG; the non–protein-bound fraction is subsequently measured in treated and untreated samples by centrifugal ultrafiltration dialysis[258] or semiautomated equilibrium dialysis.[17] The reference intervals for bioavailable testosterone in serum are listed in Table 53-7.

Androgen Index

This index is a ratio of testosterone and SHBG multiplied by 100 to give concentrations similar to measured free testos-

TABLE 53-7 Reference Intervals for Bioavailable Testosterone in Serum

terone concentrations.[357] Although this is only an indicator of free testosterone, some have found it to be useful in the evaluation of hirsutism.[236] Other reports have indicated that the free androgen index is not a reliable parameter of free testosterone because of its variation as a function of SHBG concentration.[174,231,346]

Mathematical Modeling

Methods based on mathematical modeling use algorithms to derive non–SHBG-bound testosterone. SHBG has been shown to be highly correlated with the percentage of free testosterone. Using this relationship, an algorithm is used to calculate percent free testosterone from the SHBG concentration. The calculated percent free value is then multiplied by total testosterone to obtain the concentration of free testosterone. For example, the algorithm used by Nanjee and Wheeler is:[236]

$$\% \text{ Free testosterone} = 6.11 - 2.38 \log \text{SHBG} \times 10^{-9}$$

More complex calculations have been used to calculate the concentration of free testosterone that are based on the law of mass action. For example, Vermeulen and co-workers derived the following calculation of the concentration of free testosterone from the measurement of the concentrations of total testosterone and SHBG:[346]

$$FT = \frac{T - ((K_A)(C_A) + 1)(FT)}{(K_T)(SHBG) - (K_T)(T) + ((K_A)(C_A)+1)(K_T)(FT)}$$

where

FT = Concentration of free testosterone (mol/L)
T = Concentration of total testosterone (mol/L)
K_T = Association constant of SHBG for T (suggested value = 1×10^9 L/mol)
SHBG = Concentration of SHBG (mol/L)
K_A = Association constant of albumin for T (suggested value = $3.0 - 3.6 \times 10^4$ L/mol)
C_A = Concentration of albumin (MW = 69,000 Da)

Solving this equation for FT yields a quadratic equation* in the form:

$$Ax^2 + Bx + C = 0$$

*The authors acknowledge the assistance of Curtis Parvin, Washington University and Jim Boyd, University of Virginia in solving the quadratic equation.

Assuming x = FT, the formula for the positive x would be:

$$x = FT = \frac{-B + \sqrt{B^2 - 4AC}}{2A}$$

where

$$A = [(K_A)(C_A) + 1]K_T$$
$$B = (K_A)(C_A) + (K_T)(\text{SHBG}) - (K_T)(T) + 1$$
$$C = -T$$

Although complex, these calculations have demonstrated a very good correlation (both linearity and value agreement) with equilibrium dialysis measurements and are considered a reliable indicator of free testosterone.[346] The reader is directed to other references for further details on this method.[311,375] Conditions resulting in abnormal plasma protein concentrations, such as nephrotic syndrome, cirrhosis, and pregnancy require adjustments in the assumption for albumin concentration.

Measurement of Testosterone in Saliva

Salivary testosterone concentration correlates with free testosterone concentrations in plasma and has been advocated as an indicator of androgen status.[244] In a multicenter evaluation that examined nine different laboratories using various RIA methods with and without extraction, good correlation was found between laboratories despite widely varying methods.[67] Reference intervals of 4 to 14 ng/dL[267] and 2 to 6 ng/dL[163] have been reported for testosterone in saliva of men. Measurement of salivary testosterone in women has been less reliable, with no consensus on salivary concentrations available.[237,267,304,357] However, one commercial laboratory reports a reference interval of 0.5 to 1.8 ng/dL for women.[163] An enzyme immunoassay method for determination of testosterone concentration in saliva has been described and evaluated in female specimens.[304]

Measurement of Testosterone Precursors and Metabolites in Blood

Several biosynthetic precursors and metabolites of testosterone have been measured using specific immunoassays (either directly or after sample extraction), chromatography, or both. Examples include DHT, 3α-androstanediol glucuronide,[263] androstenedione,[335] and DHEA. DHT is a product of testosterone, produced in androgen-sensitive tissues, and is a potent androgen. 3α-Androstanediol glucuronide is a metabolite of DHT and provides a marker of peripheral disorders of androgen action and formation, particularly hirsutism. Patients with hirsutism of either idiopathic nature or secondary to PCOS have elevated 3α-androstanediol glucuronide concentrations. Androstenedione is a product of 17α-hydroxyprogesterone and DHEA and is the immediate precursor of testosterone. Circulating concentrations have been found increased in several pathological disorders, such as CAH, adrenal tumors, and polycystic ovarian disease.

Reference intervals for these analytes in serum are listed in Table 53-8[261,336] and in Chapter 56.

Measurement of Dehydroepiandrosterone and Its Sulfate

Measurements of DHEA or its sulfated conjugate, DHEA-S, in serum and plasma are important to investigations of adrenal androgen production, such as the assessment of hyperplasia, adrenal tumors, adrenarche, delayed puberty, or hirsutism. DHEA-S in circulation originates primarily from the adrenal glands, although in men some may be derived from the testes; none is produced by the ovaries. DHEA is secreted almost entirely by the adrenal glands.

DHEA concentrations exhibit a circadian rhythm that reflects the secretion of ACTH and also varies during the menstrual cycle. DHEA-S concentrations do not exhibit a circadian rhythm because of their longer circulating half-life.[250] Concentrations in serum are increased in cord blood and drop precipitously at birth. Concentrations in premature infants are in general much higher than those in full-term infants. Pregnancy and oral contraceptives induce a modest reduction and glucocorticoids a marked decrease. Patients with PCOS often have elevated concentrations of DHEA-S, suggesting an adrenal androgen contribution to the defect in this disorder. Concentrations of DHEA-S are also elevated in CAH and with adrenocortical tumors (concentrations higher with adrenal carcinoma than with adrenal adenomas),[250] whereas concentrations are not elevated in women with virilizing ovarian tumors. Glucocorticoid administration for several days suppresses concentrations in patients with adrenal hyperplasia. DHEA is commercially available in health food stores; therefore increased serum concentrations may be caused by exogenous use.

Methodology

Immunoassay is the method of choice for measurements of DHEA and DHEA-S. Other methods include gas-liquid chromatography,[107] double-isotope derivative methods,[119] and competitive protein-binding assays.[34,36,277] The latter actually measures 5-androstenediol derivatives and uses SHBG as a naturally occurring binding protein. A reference method based on high-performance liquid chromatography-mass spectrometry has been used for independent evaluation of routine methods.[302] Immunoassays for DHEA-S demonstrate significant cross-reactivity with DHEA, androstenedione, and androsterone, yet the relative concentrations of these steroids cause a minimal effect on assay performance.

Radioimmunoassay

Analysis of DHEA-S in serum or plasma is routinely performed using direct RIA; neither extraction nor chromatography is required in most methods. In the direct procedures of Buster and Abraham[41] and Cattaneo and co-workers,[52] plasma samples are assayed with an antibody generated against DHEA-3-hemisuccinate coupled to albumin. This antiserum completely cross-reacts with unconjugated DHEA, but only minimally with androstenedione. Because of the presence of relatively large amounts of DHEA-S, this steroid has been measured directly in plasma by diluting out interfering steroids that are present in relatively low concentration.

A variety of commercial RIA kits are available for measuring DHEA-S in serum or plasma. In one procedure (Coat-a-count; Diagnostic Products Corp.), ^{125}I-labeled DHEA-S competes with DHEA-S in the patient sample for sites on antibody-coated tubes.[82] After incubation for 30 minutes at 37 °C, separation of bound from free DHEA-S is achieved by simply decanting. This solid-phase kit is equipped with protein-based calibrators having DHEA-S concentrations ranging from 5 to 1000 μg/dL (0.14 to 27 μmol/L). The assay detects as little as 2.1 μg/dL (0.05 μmol/L). Intraassay and interassay coefficients of variation are less than ± 7% at concentrations ranging from 204

to 761 µg/dL (5.5 to 20.5 µmol/L). The antiserum is stated to be highly specific for DHEA-S, with very low cross-reactivity to other compounds, including DHEA (0.08%). Bilirubin, protein, and hemolysis have no clinically significant effects on the assay. Supraphysiological concentrations of free fatty acids and lipids, however, interfere with the procedure. Discordance has been reported among different RIA methods for DHEA-S, and in several disorders the presence of interfering DHEA-like steroids in serum has been confirmed.[55]

Nonisotopic Immunoassay

Nonisotopic methods have also been described. For example, a homogeneous (nonseparation) fluorescence polarization immunoassay for DHEA-S that uses a rabbit polyclonal antibody and a DHEA-fluorescein tracer is available.[135] The measured polarization is inversely related to DHEA-S concentration. This fully automated system has a dynamic range of 1 to 1000 µg/dL (0.03 to 27 µmol/L), and interassay coefficients of variation are less than ± 10% over a broad concentration interval (25 to 1000 µg/dL; 0.7 to 27 µmol/L). Assay time is about 15 minutes for a single sample and 30 minutes for 20 samples.

A heterogeneous solid-phase enzyme immunoassay for DHEA-S is commercially available.[87] This method uses horseradish peroxidase as enzyme label, rabbit anti-DHEA-S-coated microtiter wells, and tetramethylbenzidine as substrate. The assay is stated to have a lower limit of detection of 15 ng/dL (40.6 nmol/L). An automated method employing chemiluminescent detection of alkaline phosphatase–labeled conjugate has been described. This assay reported a lower limit of detection of 2 µg/mL (54.0 nmol/L).

Specimen Collection and Storage

Serum or plasma (preserved with EDTA) is suitable for DHEA or DHEA-S immunoassays.[163,261] No steroids, ACTH, estradiol, or gonadotropin medications should be given for 48 hours before sample collection.[163] Early morning collection, before 1030 hours, is preferred for DHEA.[218,261] Refrigerated samples (4 °C to 8 °C) are stable for up to 14 days, those frozen at −20 °C are stable for >1 years.[92,138,378]

Reference Intervals

Reference intervals for serum concentrations of DHEA-S and DHEA are listed in Table 53-9.[163,336]

Comments

Enzyme immunoassay and RIA kits for the measurement of salivary DHEA and DHEA-S are commercially available for research purposes.[90,290] Analysis of DHEA by immunoassay usually requires pretreatment of serum samples, because the serum concentration of DHEA is 1000-fold lower than that of DHEA-S. Several extraction and chromatographic procedures have been suggested for this purpose. Celite is the preferred adsorbent, and dichloromethane and ethyl acetate are common choices for extraction solvents. Commercial RIA kits using solid-phase separation techniques and ^{125}I-

labeled DHEA are widely available for convenient measurement of serum concentrations. A typical kit method can detect as little as 3 ng/dL (0.1 nmol/L) of DHEA.[81] Cross-reactivity of antisera with related steroids is relatively low, with some exceptions (androstenediol, about 6%; androstenedione, about 2%; and testosterone, about 1%). Interextraction precision, expressed as a coefficient of variation, is less than ± 12% at a DHEA concentration of 120 ng/dL (4.1 nmol/L).

Measurement of 17-Ketosteroids in Urine

The 17-KSs are metabolites of precursors secreted by the adrenal glands, the testes, and to some extent the ovaries. In men, approximately one third of the total urinary 17-KSs represent metabolites of testosterone secreted by the testes, whereas most of the remaining two thirds are derived from the steroids produced by the adrenal glands. In women, who normally excrete smaller quantities than men, the total 17-KS concentrations are derived almost exclusively from the adrenal glands.

The bulk of the urinary 17-KSs consists of androsterone, epiandrosterone, etiocholanolone, DHEA, 11-keto- and 11β-hydroxyandrosterone, and 11-keto- and 11β-hydroxyetiocholanolone. DHEA and 11-oxygenated 17-KSs are produced only by the adrenal glands, whereas the others also arise from precursors (androstenedione and testosterone) elaborated by the gonads. Thus the main purpose of measuring these steroid metabolites is to assess adrenal androgen production.

Decreased concentrations of 17-KSs usually are found in men with primary hypogonadism (Klinefelter's syndrome and castration), in secondary hypogonadism (panhypopituitarism), and in women with pituitary hypoadrenalism (Addison's disease). *Increased concentrations* are found in patients with testicular tumors (interstitial cell tumor and chorioepithelioma), adrenal hyperplasia, and adrenal carcinoma, and in some women with hirsutism.

All 17-KSs are not androgens, and not all androgens are 17-KSs. DHEA and androstenedione are 17-KSs with only weak androgenic properties, and etiocholanolone is a 17-KS with no androgenic effects. The potent androgens, testosterone and DHT, are not 17-KSs. A specific measurement of testosterone and DHT in blood is required to evaluate the production of these androgens. The measurement of DHEA-S in blood serves as a more convenient marker for adrenal androgen production than does urinary 17-KS excretion both because a 24-hour urine collection is not required, and because of the many drugs that interfere with the 17-KS assay.[207] For these reasons, many clinicians now prefer to have concentrations for plasma DHEA-S to interpret rather than those for urinary 17-KS.

Methodology

Several chemical methods are available for estimating the concentration of total 17-KSs in urine. Final quantitation in some of these methods is based on the color reaction originally described by Zimmerman. The method described by Sobel and co-workers[310] has been shown to be adequate for routine clinical use. In this procedure, acid cleavage of glucuronic and sulfuric acid conjugates of 17-KSs is followed by extraction, washing with alkali, and finally color development. Estrone, which is an "acidic" 17-KS, is removed by alkali treatment because of its phenolic nature, and thus is eliminated before the photometric reaction of the remaining "neutral" 17-KS fraction. The color formation is based on the reaction of 17-KS with *m*-dinitrobenzene in alcoholic potassium hydroxide to produce a reddish-purple color with maximum absorption at 520 nm.[214] Marlow has demonstrated that the development of color depends on the presence of an active methylene group adjacent to a carbonyl group.[214] When the ketone group is situated at other positions (e.g., Δ^4-3-keto in testosterone, progesterone, and cortisol), the color development is less intense and the absorption maximums differ. Quantitation is carried out by comparison of the optical absorbance obtained with the sample with that obtained with a known amount of pure calibrator, such as DHEA. For specific analytical details, the interested reader is referred to the first edition of this textbook.[57] The reference interval for the urinary excretion of 17-KSs is 10 to 25 mg/day (35 to 87 μmol/day) in men and 6 to 14 mg/day (21 to 49 μmol/day) in women.[336] Various drugs interfere with the 17-KS assay. Agents that produce a positive interference include chlorpromazine, ethinamate, meprobamate, nalidixic acid, penicillin, phenaglycodol, and spironolactone. Agents that produce a negative interference include chlordiazepoxide, progestational agents, propoxyphene, and reserpine.[250]

Measurement of Anabolic Steroids

Exogenous steroids such as testosterone and DHT that are used to improve athletic performance are a challenge to detect and measure for the laboratory. The ratio of testosterone to epitestosterone, its 17α-epimer, has been used for detection of testosterone abuse. A ratio of testosterone to epitestosterone >6:1 suggests exogenous testosterone use and further testing should be performed for confirmation.[50] Others have suggested a ratio of testosterone to LH in the urine as an indication of testosterone doping. Detailed studies of these ratios are available.[177] GC-MS remains the most widely used method for screening and confirmation. For additional information regarding methods, the reader is directed to reviews on the subject.[3,32,49,50,51]

Measurement of Estrogens in Blood

Methodology

Both chromatographic and immunoassay methods are used to measure estrogens in blood.

Chromatographic Methods

GC-MS methods associated with isotope dilution provide the most accurate and reliable measurement of estradiol.[77,303,332,371] The main steps in these reference methods

are solvent extraction, chromatographic fractionation, and chemical derivatization before instrumental analysis. Validation of routine methods by this technique has become important in many external quality assurance programs. For routine purposes, these chemical and physical methods have been largely replaced by immunoassays, which are easier and faster than chromatographic methods.

Immunoassay

Immunoassays consist of both indirect (extraction required) and direct (no extraction required) methods. The most common antigen used to prepare antibodies for estradiol assays is estradiol-6-(*O*-carboxymethyl)oxime conjugated to bovine serum albumin.[265] Cross-reactivity with other C_{18} steroids is usually minimal as the 3- and 17-hydroxyl groups are left free. A 2002 CAP survey confirms that direct enzyme immunoassays have largely replaced RIAs for routine measurement of estradiol concentrations. The limitations of automated, nonisotopic immunoassays will be discussed later in this section. Evaluation of estrogen concentrations in men, postmenopausal women, and children requires use of more sensitive RIAs. Many of the early immunoassays used organic solvents for selective extraction of estradiol from serum. This step not only removes estradiol from endogenous binding proteins but also removes other compounds that interfere with the method.

To measure estradiol directly without extraction and chromatography, the steroid must be displaced from its binding proteins. The displacing agents used in commercial methods are often not disclosed, but in some systems effective displacement is achieved by adding 8-anilino-1-naphthalene sulfonic acid (ANS) or a large excess of a competing steroid such as DHT to the sample.[265]

A number of direct RIA kit methods are commercially available for measuring serum estradiol.[76,265] Assay conditions used in these kits vary, with sample volumes ranging from 25-200 µL and incubation times of 45 to 190 minutes. One of the simplest kits available (Coat-a-count; Diagnostic Products Corp.) is a simple two-step assay that requires only the pipetting of an aliquot of sample into an antibody-coated tube followed by a single 3-hour incubation at room temperature; no centrifugation is necessary.[83] This kit is equipped with human serum-based calibrators that have estradiol concentrations ranging from 20 to 3600 pg/mL (0.07 to 13.20 nmol/L); intraassay and interassay precision across a range of estradiol concentrations is less than ±9%.

Bilirubin, hemolysis, and lipemia do not affect this assay, but free fatty acids have significant effects on it. Cross-reacting steroids in samples from neonates have also caused interference. Some direct assays exhibit interference from SHBG, resulting in overestimation of estradiol concentrations at low SHBG concentrations and in underestimation at high concentrations. There has also been a report of an unknown water-soluble interfering substance, which caused falsely increased estradiol results in a variety of direct assays.[199] This interferant is removed by simple extraction with an organic solvent.

Caution should also be exercised when assaying samples from subjects who are receiving oral contraceptives or estrogen replacement therapy because cross-reacting steroids may cause elevated results. Most notably, cross-reactivity with estrone is as high as 10% for some assays, but much lower (<1%) in others. This is likely due to a difference in the specificity of the antibody used for estradiol. Similar effects have been observed for metabolites conjugated at the 3 position, like estrone-3-sulfate and estrone-3-glucuronide.[153,200]

A number of nonisotopic immunoassays for estradiol have been developed and adapted for use on fully automated immunoassay systems. All are heterogeneous assays (separation step needed), but most are direct assays and do not require preliminary extraction. Most procedures offer the convenience of solid-phase separation methods. For routine clinical applications, the greatest experience is with enzyme immunoassays. Most commercial enzyme immunoassays use horseradish peroxidase or alkaline phosphatase to label estradiol antigens; enzyme activity is determined using a variety of photometric,[31,132,200] fluorescent,[11,12,269,271] or chemiluminescent substrates.[158]

Immunoassays using fluorescent labels[18] (e.g., europium chelates and time-resolved fluorescent immunoassay) and chemiluminescent labels[29,73] have also been described. England and co-workers describe a semiautomated "ultrasensitive" chemiluminescent immunoassay for estradiol.[104] This method is reportedly capable of accurately measuring low concentrations (<50 pmol/L) of estradiol observed in perimenopausal and postmenopausal women, healthy men, and children. Taieb and co-workers compared the detection limits and functional sensitivities for nine automated estradiol immunoassays.[323] They concluded that the functional sensitivities, defined as the lowest concentration of analyte that can be measured with a run-to-run imprecision of 20%, were 2- to 4-fold higher than the detection limits of the tests. It is also important to note that none of the assays analyzed in this study had the functional sensitivity required for the evaluation of serum estradiol measurements in men, menopausal women, and children.[93] The functional sensitivities ranged from 5.5 to 46 pg/mL (20 to 169 pmol/L). These assays have been optimized for clinical applications, such as the monitoring of ovarian stimulation in which high estradiol concentrations are expected. A comparison of two direct immunoassay methods for measuring serum estradiol concentration revealed that such assays are useful during monitoring in vitro fertilization progress, but that the values obtained depend on the method used.[324] The authors suggest that, until estradiol assays are better standardized, reference intervals and cutoff points used as clinical decision criteria must be evaluated and modified, if necessary, for each assay.

Specimen Collection and Storage

Serum or plasma (with EDTA or heparin as anticoagulant) is used. Samples should be centrifuged and separated within

24 hours. Samples may be stored refrigerated for 24 hours or frozen for up to 1 year.[92,138,378] Estradiol concentrations are increased in liver cirrhosis, and oral contraceptives have been found to alter concentrations.[163] No steroid, ACTH, gonadotropin, or estradiol medications should be given within 48 hours of sample collection.[163]

Reference Intervals

Reference intervals for serum concentrations of estradiol and estrone are listed in Table 53-10, in Chapter 56, and elsewhere.[163,336]

Measurement of Estriol

Measurement of estriol has little clinical value, except during pregnancy (see Chapter 54), because in nonpregnant women estriol is derived almost exclusively from estradiol. Both RIA and nonisotopic immunoassay methods for estriol measurement in serum and plasma are commercially available. The RIA methods employ both double-antibody and coated-tube technologies using ^{125}I-labeled estriol conjugate.[89,91] The manufacturers claim that the reportable range for these assays is ~0.1 to 30 ng/mL. Competitive enzyme immunoassays are also commercially available. Chemiluminescent detection via an alkaline phosphatase–labeled conjugate has been described.[86] Additionally, an enzymatic method based on biotin-streptavidin binding that photometrically monitors the turnover of horseradish peroxidase in the presence of tetramethylbenzidine (TMB) is available.[88] A 2002 CAP survey reports that automated enzymatic immunoassay methods account for the majority of unconjugated estriol measurements, with <30% performed by RIA.[64]

Specimen Collection and Storage

Estriol serum or plasma specimens are stable at room temperature for 24 hours, and can be refrigerated for 2 days and frozen at –20 °C for up to 1 year.[138] Patients should not be fasting before specimen collection.

Comments

Estrone determinations are limited to diagnosis of postmenopausal bleeding and the menstrual dysfunction caused by extraglandular estrone production. Normally, blood estrone concentrations parallel estradiol concentrations throughout the menstrual cycle, but at slightly lower concentrations. For a specific analysis of estrone, the interested reader is directed to other references.[61,94]

Measurement of Estrogens in Urine

Several chemical methods for urinary estrogen determination have been described.[208] In most, detection is carried out by either fluorometry or photometry. When heated with sulfuric acid, estrogens form an orange-yellow color with intense yellowish-green fluorescence. Such acid-induced fluorescence is sufficiently sensitive to permit detection of as little as 0.005 μg of estrogens. However, nonspecific fluorescence and a number of other variables—such as length of exposure of acid and steroids to elevated temperatures, the amount of water added, and the presence or absence of solvents—are sources of analytical difficulty in using fluorometry for routine analysis. Of the photometric methods available, the *Kober reaction* is best known. For details on this

reaction, the reader is directed to the second edition of this book.[361]

Total and fractionated urinary estrogens have been quantitated by RIA after hydrolysis or enzymatic digestion of estrogen glucuronides; analytical specificity for estradiol, estrone, and estradiol is attained by performing a celite chromatograph step before the RIA. A time-resolved fluoroimmunoassay for unconjugated estrogens in urine has been proposed as an alternative to RIA and to the fluorometric assay of total estrogen.[333] Several nonradioactive enzyme immunoassays for urinary estrone conjugates have been described.[59,234,245]

Measurement of Estrogens in Saliva

Measurement of steroids in saliva is noninvasive and suitable for the collection of frequent samples.[205,262] Serial monitoring of estradiol has been used for clinical diagnosis and treatment of infertile women with anovulatory cycles, during in vitro fertilization, or when monitoring hormone replacement therapy of postmenopausal women. Because salivary concentrations of estradiol closely reflect the free fraction of the steroid in plasma, the concentration in saliva is only 1% to 2% of the concentration in blood (1 to 36 pmol/L in nonpregnant women). Hence this requires a sensitive assay for accurate measurement.

Methodology

In general, kits for the measurement of estradiol in saliva are not commercially available. However, Tamate and coworkers have reported the use of a direct enzyme immunoassay that shows promise for the measurement of salivary estradiol.[327] This assay uses monoclonal anti–estradiol-coated microtiter plates and an estradiol-peroxidase conjugate. No extraction is required. These authors reported a salivary estradiol peak of 15 to 31 pmol/L in the preovulatory phase and from 9 to 33 pmol/L in the midluteal phase. Lu and co-workers have described a double-antibody RIA using ^{125}I-labeled estradiol conjugate for the determination of salivary estradiol.[210]

Specimen Collection and Storage

Saliva should be collected after thoroughly rinsing the mouth and frozen immediately. Freezing may help to break down mucin and give a more fluid specimen. Samples are thawed and then centrifuged to remove debris, and can be heat treated at 56 °C for 2 hours to reduce interference by the saliva matrix.

Reference Intervals

Reference intervals for salivary concentrations of estradiol have been reported to be 20 to 70 pg/dL in men and 50 to 300 pg/dL in women.[163]

Comment

Assays for the measurement of estradiol are reported to be highly reagent dependent.[267]

Measurement of Progesterone in Blood

Measurement of progesterone in serum or plasma is considered to be the most reliable technique to assess its rate of production.

Methodology

Double–isotope derivative methods[370] and competitive protein-binding assays[79] have been applied to the measurement of serum progesterone, but require extensive purification of the steroid and are labor intensive. Gas chromatography procedures using flame ionization, electron capture, or nitrogen detection have been used to improve the accuracy of progesterone analysis.[36,79] These methods also are time consuming and often require solvent extraction, chromatography, and derivatization before the steroid can be quantitated. GC-MS has been recommended as a reference method for progesterone determination. The method of Thienpont and associates[331] makes use of heptafluorobutyric ester derivatives and 19-$^{2}H_3$-progesterone as internal standards.

For routine measurement of progesterone in the clinical laboratory, immunoassays using steroid-specific antibodies are preferred. Initial immunoassays for serum progesterone measurement used organic solvents to remove the steroid from endogenous binding proteins, such as corticosteroid-binding globulin and albumin. Direct (nonextraction) measurement of progesterone in serum or plasma is considered the method of choice for routine applications. A number of different antigens have been used to prepare antisera for progesterone assays. Cross-reactivity is most prominent with 5α-pregnanediol, ranging from 6% to 11%. Both RIA and nonisotopic immunoassays are available for measuring progesterone. A 2002 CAP survey reports that enzyme immunoassays account for the majority of progesterone assays used today.[64]

Radioimmunoassay Methods

Most RIA procedures for progesterone use antibodies generated against a progesterone-11α-hemisuccinate conjugated to bovine serum albumin. Other points on the steroid molecule (e.g., C-3, C-6, C-7, and C-20) have also have been used to link carrier proteins. Some of the antisera produced with these conjugates may cross-react with other C_{21}-corticosteroids present in the sample. If these corticosteroids become a problem, a simple solvent extraction or chromatographic purification procedure before immunoassay can be conducted.[54] Fortunately, these interfering steroids are much more polar than is progesterone. The use of a nonpolar solvent, such as petroleum ether or hexane, quantitatively extracts progesterone, whereas the polar corticosteroids remain mostly in the serum sample.

Historically, tritiated progesterone was the label of choice, but various ^{125}I radioligands have since become more widely used because of the convenience and cost saving of γ-over β-counting. In particular, ^{125}I-labeled progesterone-glucuronyl-tyramine yields satisfactory assays with a

number of different progesterone antisera.[369] Other iodinated derivatives of progesterone have also been prepared and combined with antisera from several sources to produce homologous and heterologous bridge systems with variable sensitivity and specificity. In general, poor sensitivity is observed in homologous systems, because the common structural features of both the immunogen and the tracer result in the latter having a much higher affinity than the analyte for the antibody. A variety of procedures have been used to separate the free and antibody-bound radioligand fractions. Dextran-coated charcoal is the conventional separation technique for assays using tritiated labels. Double-antibody and solid-phase separation methods are preferred for assays using radioiodine.

A number of direct RIA kits are simple to perform, rapid, precise, accurate, and commercially available.[272,369] Most of these kits use either 8-anilino-1-naphthalene sulfonic acid or danazol to displace progesterone from binding proteins. One of the simplest direct kits (Coat-a-count; Diagnostic Products Corp.) uses antibody-coated tubes, two pipetting steps, and a single 3-hour incubation at room temperature.[84] This kit includes serum-based calibrators having progesterone concentrations ranging from 0.1 to 40 ng/mL (0.3 to 127 nmol/L).

Direct RIAs for progesterone have been reported to give quantitative recovery of both exogenous progesterone added to serum and patient serum.[266] Assay accuracy, however, is affected by the nature of the matrix used in preparing the calibrators. For progesterone assays, satisfactory accuracy may be achieved by using pooled sera for men who have progesterone concentrations <0.3 ng/mL (<1 nmol/L). The precision of direct assays is superior to that of extraction assays. Both intraassay and interassay coefficients of variation are below ±10%.

Nonisotopic Immunoassays

Several nonisotopic immunoassays are available on fully automated immunoassay systems. Most of these nonisotopic assays measure progesterone directly without extraction. All are heterogeneous assays and require separation of free and antibody-bound fractions. Enzymes appear to be the most widely used nonradioactive label. Alkaline phosphatase and horseradish peroxidase coupled to progesterone or antiprogesterone antibodies are particularly popular. An assortment of photometric,[155,200,341] fluorescent,[113,272,366] and luminescent[29,212] substrates are available for monitoring the enzyme activity of the antibody-bound fraction. Direct time-resolved fluoroimmunoassays for progesterone have also been described.[74,172]

Although automated immunoassays are less labor intensive than RIAs and yield results in less time without the need for radioactivity, these assays do not have adequate functional sensitivity for applications involving low progesterone concentrations (i.e., men, postmenopausal women, and children). Taieb and co-workers analyzed the detection limits and functional sensitivities for eight automated progesterone methods.[323] They reported that the functional sensitivities (0.32 to 1.43 nmol/L) were from 2- to 4-fold higher than the manufacturer-stated detection limit (0.19 to 0.48 nmol/L). Automated progesterone assays have been optimized for use in in vitro fertilization protocols as a rapid, cost effective way to evaluate ovarian stimulation and monitor ovulation.

Plasma concentrations of 17α-hydroxyprogesterone are measured to evaluate 21-hydroxylase deficiency. For specific methods regarding this analyte, the reader is referred to a review by Wallace.[350]

TABLE 53-11 Reference Intervals for Progesterone in Serum

	ng/dL	nmol/L
Prepubertal child (1-10 yr)	7-52	0.2-1.7
Adult man	13-97	0.4-3.1
Adult woman		
Follicular phase	15-70	0.5-2.2
Luteal phase	200-2500	6.4-79.5
Pregnant woman		
First trimester	725-4400	23.0-139.9
Second trimester	1950-8250	62.0-262.4
Third trimester	6500-22 900	206.7-728.2

Specimen Collection and Storage

Serum or plasma (with heparin or EDTA as anticoagulant) has been used, but should be separated within 24 hours.[163] The patient need not be fasting, and no special handling procedures are necessary.[1,84] Samples can be stored refrigerated for up to 3 days at 4 °C to 8 °C or for up to 1 year at 20 °C.[92,138,378] Patients should not be on any corticosteroid, ACTH, estrogen, or gonadotropin medication for at least 48 hours before specimen collection.[163]

Reference Intervals

Reference intervals for serum concentrations of progesterone are listed in Table 53-11[336] and in Chapter 56.

Measurement of Progesterone in Saliva

Serial sampling of progesterone has been used to (1) investigate luteal defects in women with undefined infertility, (2) monitor the return of fertility after parturition, and (3) assess the bioavailability of oral progesterone.[24,164,205] Several have advocated the use of early-morning saliva for measuring 17-hydroxyprogesterone to aid in the diagnosis of CAH.[251,379] Salivary progesterone concentrations are in general thought to reflect free "unbound" progesterone in the blood,[351] although Evans reported that the amount of progesterone transported into saliva is not determined

exclusively by the unbound concentration in plasma and cautioned against the direct correlation between the saliva and serum unbound fraction.[106]

Methodology

Both RIA and enzyme immunoassay methodologies have been applied to the determination of progesterone in saliva. Although sample extraction procedures are often necessary to eliminate protein influences,[117] direct methods are favored in routine laboratories and have been described.[210,249,326] Rigorous standardization of sample collection and preparation is important for obtaining meaningful results for clinical purposes.[295]

Specimen Collection and Storage

Saliva specimens should be collected after a thorough mouth rinsing, centrifuged to remove debris, and frozen immediately. Samples can be heat treated at 56 °C for 2 hours to reduce interference by saliva matrix.

Reference Intervals

Salivary progesterone measurements are not widely commercially available, and no standardized reference intervals exist. However, the reference concentration for salivary concentrations of progesterone in men is reported to be <0.5 ng/dL.[163] In women, the reported reference intervals are 0.5 to 4.0 ng/dL in the follicular phase and 6 to 12 ng/dL in the luteal phase.[163]

CHAPTER 54

Clinical Chemistry of Pregnancy

Edward R. Ashwood, M.D., and George J. Knight, Ph.D.

The clinical laboratory has an important role in managing pregnancy.[19] In contrast to most clinical situations, when treating an expectant mother, a physician must simultaneously care for more than one patient. The health of the mother and her fetus are intertwined, each affecting the other; thus pregnancy management must consider both. This chapter reviews the biology of pregnancy and discusses laboratory tests used to detect, evaluate, and monitor pregnancy, both normal and abnormal. These include common tests, such as chorionic gonadotropin (CG), hematocrit, blood type, and glucose tolerance testing; screening tests, such as the "quad test" (alpha fetoprotein [AFP], CG, unconjugated estriol [uE_3], and dimeric inhibin A [DIA]); and esoteric tests, such as fetal lung maturity tests and amniotic fluid bilirubin examination.

HUMAN PREGNANCY

To appreciate the role of laboratory tests in pregnancy health care, it is necessary to understand fundamental topics, such as conception, embryo development, fetal growth, the role of the placenta, the importance and composition of amniotic fluid, maternal adaptation to pregnancy, and functional maturation of the fetus.

Conception, Embryo, and Fetus

Normal human pregnancy lasts approximately 40 weeks, as measured from the first day of the last normal menstrual period, a date commonly represented by the abbreviations LMP or LNMP. The anticipated date of birth of an infant is commonly referred to as the *expected date of confinement*, or EDC. During pregnancy, a woman undergoes dramatic physiological and hormonal changes. When talking with patients, physicians customarily divide pregnancy into three time intervals called *trimesters*, each of which is slightly longer than 13 weeks. By convention, the first trimester, 0 to 13 weeks, begins on the first day of the last menses.

Ovulation occurs on approximately the 14th day of the regular menstrual cycle (see Chapter 53). If conception occurs, the ovum is fertilized, usually in the fallopian tube, and becomes a *zygote*, which is then carried down the tube into the uterus. The zygote divides, becoming a *morula*. After 50 to 60 cells are present, the morula develops a cavity, the primitive *yolk sac*, and thus becomes a *blastocyst*, which implants into the uterine wall about 5 days after fertilization. The cells on the exterior wall of the blastocyst, *trophoblasts*, synergistically invade the uterine endometrium and develop into chorionic villi, creating the placenta. Trophoblasts can be subdivided into syncytiotrophoblasts and cytotrophoblasts, depending on location and cellular morphology.

At this stage, the product of conception is referred to as an *embryo*. A cavity called the *amnion* forms and enlarges with the accumulation of *liquor amnii*, commonly referred to as *amniotic fluid*. Nourished by the placenta and protected by the amniotic fluid, an embryo undergoes rapid cell division, differentiation, and growth. From combinations of three primary cell types, *ectoderm*, *mesoderm*, and *endoderm*, organs begin to form, a process called *organogenesis*. At 10 weeks, an embryo has developed most major structures and is now referred to as a *fetus*. At 13 weeks, the fetus weighs approximately 13 g and is 8 cm long.

During the second trimester, 13 to 26 weeks, rapid fetal growth occurs. By the end of the second trimester, the fetus weighs approximately 700 g and is 30 cm long. Many fetal organs begin to mature. The third trimester, 26 to 40 weeks, is the period in which fetal organs complete their prenatal maturation. During this trimester, the growth rate decelerates. At the end of the third trimester, the fetus weighs

approximately 3200 g and is about 50 cm long. *Term* is the interval from 37 to 42 weeks. Normal labor, rhythmic uterine contractions, and birth occur during this period.

PLACENTA

The placenta and umbilical cord are the primary link between the fetus and mother. The placenta grows throughout pregnancy and is normally delivered through the birth canal immediately after birth of the infant.

Function

The placenta keeps the maternal and fetal circulation systems separate, nourishes the fetus, eliminates fetal wastes, and produces hormones vital to pregnancy. It is composed of large collections of fetal vessels called *villi*, which are surrounded by intervillous spaces in which maternal blood flows. For substances to move from maternal circulation to fetal circulation, they must cross through the trophoblasts and several membranes. The transfer of any substance depends largely on the concentration gradient between the maternal and fetal circulatory systems, the presence or absence of circulating binding proteins, the lipid solubility of the substance, and the presence of facilitated transport, such as ion pumps or receptor-mediated endocytosis (Box 54-1). The placenta is an effective barrier to the movement of large proteins and hydrophobic compounds bound to plasma proteins. Maternal IgG crosses the placenta via receptor-mediated endocytosis. Because of its long half-life, maternally produced IgG protects a newborn for the first 6 months of life. Antibody assays with low limits of detection may be positive in infants up to age 18 months.

Placental Hormones

The placenta produces several protein and steroid hormones (Figure 54-1). The major protein hormones are CG and placental lactogen (PL). The steroids include progesterone, estradiol, estriol, and estrone. The placenta secretes most of its products into the maternal circulation; only small amounts reach the fetal circulation. Close proximity of the maternal blood vessels to the site of placental hormone production may explain some of this preferential accumulation of hormones in the maternal blood circulation. Generally, hormone production by the placenta increases in proportion to the increase in placental mass. Therefore concentrations of hormones derived from the placenta, such as PL, increase in maternal peripheral blood as the placenta increases in size; CG, which peaks at the end of the first trimester, is an exception.

BOX 54-1 Normal Placental Transport

No Transport
- Most proteins
- Thyroid hormones
- Maternal IgM, IgA
- Maternal and fetal erythrocytes

Limited Passive Transport
- Unconjugated steroids
- Steroid sulfates
- Free fatty acids

Passive Transport
- Molecules up to 5000 Da having lipid solubility
- Oxygen
- Carbon dioxide
- Sodium and chloride
- Urea
- Ethanol

Active Transport Across Cell Membranes
- Glucose
- Many amino acids
- Calcium

Receptor-Mediated Endocytosis
- Maternal IgG
- Insulin
- Low-density lipoprotein

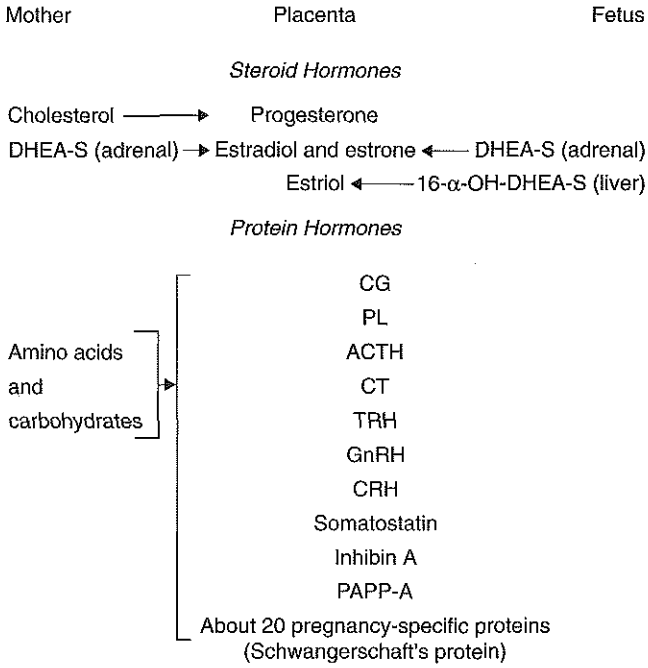

Figure 54-1 Schematic representation of steroid and protein hormone production by the placenta. *DHEA-S*, Dehydroepiandrosterone sulfate; *CG*, chorionic gonadotropin; *PL*, placental lactogen; *ACTH*, adrenocorticotropic hormone; *TRH*, thyroid-stimulating hormone; *CT*, chorionic thyrotropin; *GnRH*, gonadotropin-releasing hormone; *CRH*, corticotropin-releasing hormone; *PAPP-A*, pregnancy associated plasma protein-A.

Chorionic Gonadotropin

One of the most important placental hormones is CG. CG stimulates the ovary to produce progesterone which, in turn, prevents menstruation thereby protecting the pregnancy. The chemistry, biochemistry, and methods for CG are discussed in the section on laboratory tests later in this chapter.

Placental Lactogen

PL, also known as human placental lactogen (hPL) and human chorionic somatomammotropin (hCS), is a single polypeptide chain of 191 amino acids having two intramolecular disulfide bridges and a molecular mass of 22,279 Da. The structure of PL is exceptionally homologous (96%) with growth hormone (GH) and less so with prolactin (67%). Not surprisingly, PL has potent growth and lactogenic properties. Five genes on chromosome 17 compose a gene family that codes for both GH and PL.[246] PL production has been localized by immunofluorescence studies to the syncytiotrophoblast cells of the placenta. The increase in maternal serum PL concentration with advancing gestational age is directly correlated with the increasing mass of placental tissue and of functional syncytiotrophoblast tissue.[289] The placental secretion near term is 1 to 2 g/day, the largest of any known human hormone.

From the physiological point of view, PL has many biological activities, including lactogenic, metabolic, somatotropic, luteotropic, erythropoietic, and aldosterone-stimulating effects. Either directly or in synergism with prolactin, PL has a significant role in preparing the mammary glands for lactation. The many metabolic activities of PL closely resemble those of GH, including inhibition of glucose uptake, enhanced lipolysis leading to increased mobilization of free fatty acids, and enhancement of nitrogen retention. Because glucose is the primary energy substrate for a fetus, it has been suggested that the glucose-sparing action of PL may be a strategy to direct maternal metabolism toward greater use of fat for the mother's requirements, thereby sparing maternal glucose for fetal use. Rare normal pregnancies have been reported in which there was a complete absence of PL. Although PL was used in the past to evaluate fetal well-being, currently no apparent clinical reason exists to measure PL.[92]

Placental Steroids

The placenta produces a wide variety of steroid hormones, including estrogen and progesterone. Phenomenal amounts of estrogens are produced at term. The chemistry of these steroids is described in Chapter 53. Maternal cholesterol is the main precursor for placental progesterone production. Biosynthesis of estrogens by the placenta differs from that of the ovaries because the placenta has no 17α-hydroxylase. Thus each of the estrogens—estrone (E_1), estradiol (E_2), and estriol (E_3)—must be synthesized from C_{19} intermediates that already have a hydroxyl group at position 17. In nonpregnant women, the ovaries secrete 100 to 600 μg/day of estradiol, of which about 10% is metabolized to estriol. During late pregnancy, the placenta produces 50 to 150 mg/day of estriol and 15 to 20 mg/day of estradiol and estrone. The secretion of estrogens and progesterone throughout pregnancy ensures appropriate development of the endometrium, uterine growth, adequate uterine blood supply, and preparation of the uterus for labor. Although measurement of estriol in the third trimester was used in the past to assess fetal well-being, many obstetricians consider this practice obsolete.[93] Estriol measurements at 16 to 18 weeks gestational age are useful in predicting fetal trisomy 21 and 18 (see later discussion on maternal serum screening for fetal defects).

Amniotic Fluid

Throughout intrauterine life, the fetus lives within a fluid-filled compartment. The amniotic fluid provides a medium in which a fetus can readily move; it cushions a fetus against possible injury and helps maintain a constant temperature. This fluid is a dynamic medium whose volume and chemical composition are controlled within relatively narrow limits.

Volume and Dynamics

The volume of amniotic fluid increases progressively until 34 weeks of gestation, when it decreases slightly through the 40th week and then more sharply declines until the 42nd week.[268] The volume is 200 to 300 mL at 16 weeks, 400 to 1400 mL at 26 weeks, 300 to 2000 mL at 34 weeks, and 300 to 1400 mL at 40 weeks. The volume at any given moment is a function of several interrelated fluid fluxes. Direct measurements in primates and indirect measurements in humans have been used to derive a mathematical model of amniotic fluid volume.[211] At term, total fluid fluxes into and out of the amniotic cavity are large (~60 mL/hr) and result in complete exchange of the amniotic fluid volume twice per day. Gross unidirectional fluid volume shifts occur episodically: into the amniotic cavity by fetal urination and out of the cavity by fetal swallowing. These unidirectional shifts begin at the end of the first trimester and increase linearly until approximately 30 weeks. Fetal swallowing and urination then exponentially increase, peaking at term at about 1000 mL/day. Bidirectional water exchanges—so-called intramembranous fluxes—occur across the following surfaces: (1) placenta (mother-fetus), (2) umbilical vessels, through the substance of the umbilical cord (fetus–amniotic fluid), (3) fetal skin (fetus–amniotic fluid), and (4) fetal membranes (amniotic fluid–mother). These exchanges increase in a linear fashion throughout pregnancy. At term, they are approximately 400 mL/day. The fetal tracheobronchial tree is filled with amniotic fluid, and measurements in fetal lambs demonstrate a net flux of 50 to 80 mL/day of fluid up the trachea from the lungs. Although this is a small volume, flux is important in terms of transporting surfactant produced by the fetal lungs into the amniotic fluid.

Pathological decreases and increases of amniotic fluid volume are encountered frequently in clinical practice.

TABLE 54-1 Composition of Amniotic Fluid (Mean Values)

Component	Gestational Age (Wk) 15	25	40
Sodium, mmol/L	136	138	126
Potassium, mmol/L	3.9	4.0	4.3
Chloride, mmol/L	111	109	103
Bicarbonate, mmol/L	16	18	16
Urea nitrogen, mg/dL (mmol urea/L)	11 (3.9)	11 (3.9)	18 (6.4)
Creatinine, mg/dL (μmol/L)	0.8 (71)	0.9 (80)	2.2 (194)
Glucose, mg/dL (mmol/L)	47 (2.6)	39 (2.2)	32 (1.8)
Uric acid, mg/dL (mmol/L)	4.0 (0.24)	5.7 (0.34)	10.4 (0.61)
Total protein, g/dL (g/L)	0.5 (5)	0.8 (8)	0.3 (3)
Bilirubin, mg/dL (μmol/L)	0.13 (2.2)	0.14 (2.4)	0.04 (0.7)
Osmolality, mOsm/kg H_2O	272	272	255

From Benzie RJ, Doran TA, Harkins JL, Owen VM, Porter CJ. Composition of the amniotic fluid and maternal serum in pregnancy. Am J Obstet Gynecol 1974;119:798-810.

Intrauterine growth retardation and anomalies of the fetal urinary tract, such as bilateral renal agenesis or obstruction of the urethra, are associated with *oligohydramnios*, an abnormally low amniotic fluid volume. Increased fluid volume is known as *hydramnios* (also termed *polyhydramnios*). Conditions associated with hydramnios are as diverse as maternal diabetes mellitus, severe Rh isoimmune disease, fetal esophageal atresia, multifetal pregnancy, anencephaly, and spina bifida.

Composition

Early in gestation, the composition of the amniotic fluid resembles a complex dialysate of the maternal serum. As a fetus grows, the amniotic fluid changes in several ways (Table 54-1). Most notably, the sodium concentration and osmolality decrease and the concentrations of urea, creatinine, and uric acid increase.[34] The activities of many enzymes in amniotic fluid have been studied with respect to both gestational age and fetal status but have not been found to be clinically useful. The major lipids of interest are the phospholipids, whose type and concentrations reflect fetal lung maturity (discussed further later). Numerous steroid and protein hormones are also present in amniotic fluid.[348] Concentrations of androgens and estrogens have been measured in futile attempts to predict fetal sex. The rare syndrome of congenital adrenal hyperplasia (CAH) has been diagnosed antenatally by measuring 17-hydroxyprogesterone and pregnanetriol in the amniotic fluid near term.[171] Measurements of thyroid-stimulating hormone (TSH) and thyroxine in amniotic fluid may be useful in cases of fetal thyroid disease.[298] No other diagnostic uses for amniotic fluid hormone measurements are in common use. Prostaglandins E_1, E_2, $F_{1\alpha}$, and $F_{2\alpha}$ all are found in low concentrations in amniotic fluid and increase gradually during pregnancy. PGE_2 and $PGF_{2\alpha}$ concentrations are very high during active labor.[103] Attempts to demonstrate an acute rise in PGE_2 or $PGF_{2\alpha}$ immediately before the onset of labor, at the initiation of parturition, have been unsuccessful.

Early in pregnancy, there is little or no particulate matter in the amniotic fluid. By 16 weeks of gestation, large numbers of cells are present, having been shed from the surfaces of the amnion, skin, and tracheobronchial tree. These cells have proved to be of great utility in antenatal diagnosis. As pregnancy continues to progress, scalp hair and *lanugo* (fine hair on the body of the fetus) are also shed into the fluid and contribute to its turbidity. The production of surfactant particles in the lung, termed *lamellar bodies*, greatly increases the haziness of the fluid, which can be demonstrated by attempting to read newsprint through a clear tube containing amniotic fluid. At term, the amniotic fluid contains gross particles of *vernix caseosa*, the oily substance composed of sebum and desquamated epithelial cells covering the fetal skin.

Normal fetuses do not defecate during pregnancy. If severely stressed, a fetus may pass stool that is called *meconium*. This heterogeneous material contains many bile pigments and therefore stains the amniotic fluid green. Meconium-stained amniotic fluid is a sign of fetal stress.

Maternal Adaptation

During pregnancy a woman undergoes dramatic physiological and hormonal changes. The large amounts of estrogens, progesterone, PL, and corticosteroids produced during pregnancy affect various metabolic, physiological, and endocrinological systems. An increase in resistance to angiotensin, a predominance of lipid metabolism over glucose use, and an increased synthesis by the liver of thyroid- and steroid-binding proteins, fibrinogen, and other proteins are characteristic of pregnancy. As a result of such changes, many of the laboratory reference intervals for nonpregnant patients are not appropriate for pregnant patients. Lockitch[204] is the editor of the most comprehensive hand-

book of reference intervals in normal pregnancy. Her study group included 29 pregnant subjects who had over 70 analytes tested from 16 weeks to term and also postpartum. Mean values for selected tests expressed as a percentage of control means are presented in Table 54-2.

Hematological Changes

Maternal blood volume increases during pregnancy by an average of 45%. Plasma volume increases more rapidly than red blood cell mass; therefore, despite augmented erythropoiesis, the hemoglobin concentration, erythrocyte count, and hematocrit decrease during normal pregnancy. Hemoglobin concentrations at term average 12.6 g/dL, compared with 13.3 g/dL for the nonpregnant state. The leukocyte count varies considerably during pregnancy, from 4000 to 13,000/μL. During labor and puerperium (the interval immediately after delivery), leukocyte counts may be markedly elevated.

The concentrations of several blood coagulation factors are increased during pregnancy. Plasma fibrinogen increases approximately 65%, from 275 to 450 mg/dL; the increase contributes to the increase in sedimentation rate. Other clotting factors also increase, including factors VII, VIII, IX, and X. Prothrombin and factors V and XII do not change, whereas factors XI and XIII decrease slightly. Even though the platelet count remains unchanged in most women and the prothrombin time and activated partial thromboplastin time shorten slightly (see Table 54-2), pregnancy increases the risk of thromboembolism up to five times that of nonpregnant women.

Chemical Changes

During pregnancy, the electrolytes show little change, but there is approximately a 40% increase in serum triglycerides, cholesterol, phospholipids, and free fatty acids. Plasma albumin is decreased to an average of 3.4 g/dL in late pregnancy; plasma globulin concentrations increase slightly. Several of the plasma transport proteins increase markedly, including thyroxine-binding globulin (TBG), cortisol-binding globulin (CBG), and sex hormone-binding globulin (SHBG). Serum cholinesterase activity is reduced, whereas alkaline phosphatase activity in serum triples, mainly because of an increase in very heat-stable alkaline phosphatase of placental origin. Delivery can markedly increase creatine kinase.

Renal Function

Pregnancy increases the glomerular filtration rate (GFR) to about 170 mL/min/1.73 m^2 by 20 weeks, and therefore increases the clearance of urea, creatinine, and uric acid. The concentrations of these three analytes are therefore slightly decreased in serum for much of the pregnancy. As term approaches, GFR begins to return to nonpregnant values. Urea and creatinine concentrations rise slightly during the last 4 weeks. During this time, tubular reabsorption of uric acid increases dramatically, which increases serum uric acid compared with the nonpregnant state. Glucosuria, up to 1000 mg/day, may be present owing to increased GFR, which presents more fluid to the tubules and therefore lowers the renal glucose threshold. Protein loss in the urine can increase to up to 300 mg/day.

Endocrine Changes

The action of progesterone prevents menses and thus allows pregnancy to continue. In early pregnancy, the progesterone is produced by the corpus luteum of the maternal ovary in response to CG. In later stages the placenta directly produces enough progesterone to maintain the pregnancy.

Throughout pregnancy the plasma parathyroid hormone (PTH) is increased by approximately 40%, with almost no change in the plasma free ionized calcium fraction, thus suggesting a new set-point for the secretion of PTH. Calcitonin does not increase predictably during pregnancy, whereas 1,25-dihydroxyvitamin D is increased during pregnancy and promotes increased intestinal calcium absorption. These changes permit the transfer of large amounts of calcium to the developing fetus.

The elevated estrogen concentration stimulates increased hepatic production of CBG. The hepatic clearance of cortisol decreases. Thus, the absolute plasma concentrations of both total and free cortisol are several times higher during pregnancy. The diurnal rhythm of cortisol, higher in the morning and lower in the evening, is maintained. Increased plasma aldosterone and deoxycorticosterone concentrations are also observed.

Increasing estrogen concentrations throughout pregnancy increase the secretion of prolactin up to tenfold. Conversely, the high estrogen concentrations during pregnancy suppress the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) below the detection limit. Baseline concentrations of other pituitary hormones such as TSH remain nearly unchanged (see Table 54-2), but the growth hormone (GH) response to provocative stimuli is blunted.

Although normal pregnancy is a euthyroid state, many changes occur in thyroid function. The high concentrations of TBG raise the concentration of total thyroxine (T_4) and triiodothyronine (T_3), but a slight decrease in free T_4 concentration occurs during the second and third trimesters. A slight reciprocal increase in TSH was reported by Lockitch.[204] Thyroglobulin is significantly increased, especially in the third trimester.[138] Very few (less than 0.2%) pregnant individuals develop hyperthyroidism, and hypothyroidism is very rare.[54] Postpartum thyroid dysfunction is common and is frequently unrecognized. The fetal thyroid-pituitary axis functions independently from the mother's axis in most cases. However, if the mother has preexisting Graves' disease (hyperthyroidism caused by autoantibodies that stimulate the thyroid) those antibodies can cross the placenta and cause hyperthyroidism in the fetus. If the mother has anti-TSH autoantibodies, the infant can develop transient hypothyroidism.[204]

TABLE 54-2 Mean Serum and Plasma Laboratory Values During Normal Pregnancies Expressed as a Percentage of the Nonpregnant Mean

Analyte	Time of Gestation		
	12 wk	32 wk	Term
Sodium	97	98	97
Potassium	95	95	100

Functional Development of the Fetus

The fetal organs mature during the third trimester but not at the same rate. This section reviews the lung, liver, kidneys, and blood development of the fetus.

Lungs and Pulmonary Surfactant

In normal air-breathing lungs, a substance called *pulmonary surfactant* coats the alveolar epithelium and responds to alveolar volume changes by reducing the surface tension in the alveolar wall during expiration. Surfactant is needed because the surface tension is an inverse function of the radius of the airway. Thus small alveoli have a higher collapsing force than larger alveoli. Surfactant opposes the force and keeps the small alveoli from collapsing. Specialized alveolar cells called *type II granular pneumocytes* synthesize pulmonary surfactant and package it into laminated storage granules called *lamellar bodies.*[169,299] These storage granules are 1 to 5 μm in diameter and contain phospholipids, cholesterol, and protein.[245] Production starts as early as 20 weeks gestation,[299] but adequate amounts do not accumulate until about 36 weeks. Exudation of pulmonary fluid (via the trachea) and fetal breathing movements transport the lamellar bodies into the amniotic fluid. The internal structure of the particles rearranges into a formation described as *tubular myelin* by those using electron microscopy.[169] The newborn lung contains 100 times more surfactant per cm^3 than the adult lung. The excessive surfactant is needed at birth as the newborn transforms from breathing water to breathing air. The surfactant overcomes the surface tension produced in water-filled alveoli that are admitting air for the first time.

Pulmonary surfactant is a complex mixture of lipids and proteins, and less than 5% is composed of carbohydrates. Most of the lipid is phospholipid, and the majority of that is lecithin (phosphatidylcholine).[53] Unlike lecithin from other organs, pulmonary lecithin has two saturated fatty acids, usually palmitoyl groups. Other lipids present are phosphatidylglycerol (PG), phosphatidylinositol (PI), and phosphatidylethanolamine (see Chapter 26). Sphingomyelin is present in very small amounts (~2%). The protein fraction of lamellar bodies is approximately 4% and is composed of four surfactant-specific proteins, SP-A, SP-B, SP-C, and SP-D.[160,256]

The type II pneumocytes synthesize phosphatidylcholine in a fashion quite different from that in other cells. Most other cells synthesize phosphatidylserine from cytidine diphosphate diacylglycerol and serine. The phosphatidylserine is then decarboxylated to yield phosphatidyl ethanolamine. The final step is the successive donation of three methyl groups via S-adenosylmethionine to form phosphatidylcholine. The pulmonary biosynthetic pathway is shown in Figure 54-2. The enzyme choline phosphotransferase forms PC directly from cytidine diphosphocholine and diacylglycerol. Phosphatidylinositol formation peaks at about 35 weeks. As PI decreases in concentration, PG begins to increase.

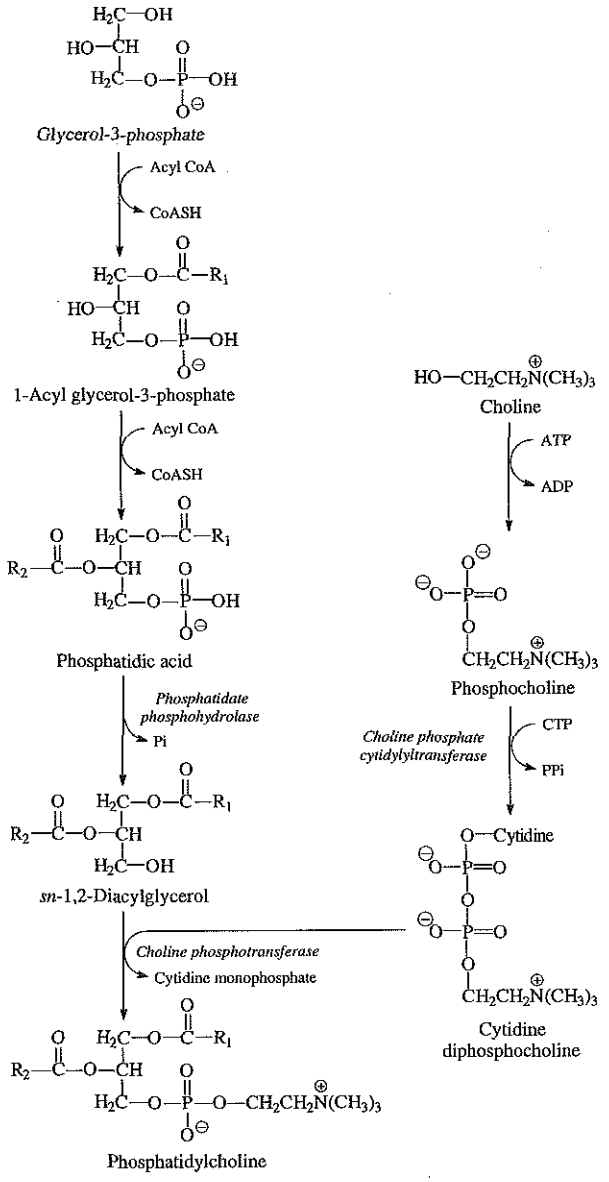

Figure 54-2 The biosynthetic pathway for phosphatidylcholine in type 2 pneumocytes.

Liver

Hematopoiesis occurs in the liver during the first two trimesters and transfers to the fetal bone marrow during the third trimester. The liver is also responsible for production of specific proteins (such as albumin and clotting factors), metabolism and detoxification of many compounds, and secretion of substances such as bilirubin. A clinically useful protein produced by the liver is AFP. Detoxification and bilirubin secretion mechanisms are immature until late in pregnancy and even in the first few months after birth. Thus premature infants often have high serum bilirubin concentrations and metabolize drugs poorly.

Kidneys

Toward the end of the first trimester the fetal kidneys begin to produce urine, which is the main component of

amniotic fluid. The early nephrons cannot produce concentrated urine, and pH regulation is also limited. Complete maturation occurs after birth. Although kidneys are not required for fetal survival, amniotic fluid is required for proper lung development. Thus newborns without kidneys die of pulmonary failure.

Fetal Blood Development

Fetal blood is produced first by the embryonic yolk sac, then by the liver, and finally by the fetal bone marrow. The yolk sac produces three embryonic hemoglobins: Portland ($\zeta_2\varepsilon_2$), Gower-1 ($\zeta_2\varepsilon_2$), and Gower-2 ($\alpha_2\varepsilon_2$). These normal embryonic hemoglobins are of little importance in clinical chemistry because they are present in fetal blood only in the first trimester.

With the switch of erythropoiesis to the fetal liver and spleen, fetal hemoglobin (Hb F) production begins. Hb F consists of two α- and two γ-chains ($\alpha_2\gamma_2$). Small amounts of adult hemoglobin, Hb A ($\alpha_2\beta_2$), are also produced, but Hb F predominates during the remainder of fetal life.

As the fetal bone marrow begins red cell production, Hb A production increases. At birth, fetal blood contains 75% Hb F and 25% Hb A. Hb F production rapidly diminishes during the first year of postnatal life. In normal adults, less than 1% of hemoglobin is Hb F. The difference between fetal and adult hemoglobin is very significant. Hb F has a higher affinity for oxygen than does Hb A. Thus in the placenta, oxygen is released from the maternal Hb A, diffuses into the chorionic villi, and binds to the fetal Hb F. In addition, 2,3-diphosphoglycerate (2,3-DPG) does not bind Hb F and therefore cannot decrease its affinity for oxygen.

MATERNAL AND FETAL HEALTH ASSESSMENT

Individuals who desire optimum health care during pregnancy should consult their physicians before conception.[11,244] Unfortunately, 49% of pregnancies in the United States are unintended—higher for unmarried women.[162] Preconception evaluation should include a medical, reproductive, and family history; physical examination; and laboratory tests. Hematocrit, blood type and Rh compatibility, erythrocyte antibody screen, Papanicolaou smear, urinalysis, rubella titer, rapid plasma reagin test, gonococcal culture, cystic fibrosis carrier status,[146] human immunodeficiency virus (HIV) antibody,[12] and hepatitis B surface antigen[7] are recommended. Depending on demographic risks, genetic testing for disorders such as Tay-Sachs disease, thalassemia, and sickle cell disease may be offered. A careful diet history is warranted. Folic acid supplementation should be recommended to reduce the risk of neural tube defects.[218]

Most individuals consult a physician a few days after a missed menses if they suspect they might be pregnant. Many laboratory tests are useful for managing normal and abnormal pregnancies. A pregnancy test result is positive (meaning that the test can detect a CG concentration of about 25 IU/L) in about half of pregnant females at the beginning of the missed menses—at about 2 weeks after conception. Screening for fetal neural tube defects and Down syndrome should be offered to all pregnant patients. Until 2002 screening was recommended at 16 to 18 weeks of gestation,[14,10] but Down syndrome screening can be performed as early as 10 weeks.[337] Glucose tolerance testing should be performed at 24 to 28 weeks. Some physicians screen patients for preterm labor risk at 24 to 30 weeks. Although PL and estriol measurements were used previously to predict fetal well-being, both tests are now obsolete for this purpose.[92,93] Maternal observation and recording of fetal movements,[8] ultrasound examination, and tests that monitor the fetal heart rate during random uterine contractions or fetal movement are the currently accepted methods for monitoring fetal well-being.

Clinical Specimens

Many different samples are available for clinical laboratory analysis before and during pregnancy. These include paternal serum and blood; maternal serum, blood, and urine; amniotic fluid obtained by amniocentesis[92,297] or from pools of fluid in the vagina after rupture of the fetal membranes; chorionic villi; fetal blood obtained by percutaneous umbilical blood sampling; and fetal tissue obtained by biopsy.[97]

The technique of amniocentesis is described in Chapter 2. Additional information can be found in the section on tests for evaluating fetal lung maturity later in this chapter.

A small sample of placental tissue, or chorionic villi, can be obtained with a catheter between 9 and 12 weeks gestation. Chorionic villi specimens can be used to identify the fetal chromosomes (the karyotype), determine enzyme levels, or detect specific gene mutations. This procedure can be performed earlier in pregnancy than can amniocentesis, but has a rate of higher fetal loss.

Diagnosis and Dating of Pregnancy

The most important aspects of pregnancy management are detection of pregnancy and establishing accurate estimates of fetal age. Obstetricians measure the length of pregnancy in terms of *weeks*, not trimesters. The most useful test for pregnancy is the CG test.

Qualitative tests for CG in blood or urine are primarily used for the confirmation of pregnancy. Urine CG tests usually suffice to diagnose normal pregnancy when it has progressed beyond the first week after the first missed period. However, qualitative serum pregnancy tests can detect pregnancy earlier, and quantitative serum tests can help reveal problems in early pregnancy.

To establish accurate dates, obstetricians rely on menstrual history, physical examination, fetal heart tones, ultrasonography, and CG concentration or detection. In the first 8 weeks of pregnancy, the CG concentration in maternal serum rises geometrically (Figure 54-3). Detectable amounts (~5 IU/L) are present 8 to 11 days after conception, which is in the third week of pregnancy as measured from the LMP.[198] Concentrations in approximately half of pregnant women

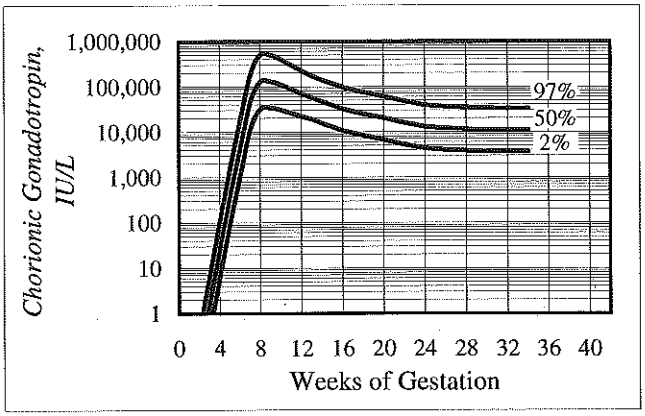

Figure 54-3 Concentration of chorionic gonadotropin (CG) in maternal serum as a function of gestational age. Lines represent the 2nd, 50th, and 97th percentiles. The maternal serum values from 14 to 25 weeks are medians calculated from 24,229 pregnancies from testing performed at ARUP Laboratories Inc. from January to October 1997. *(Redrawn from Ashwood ER. Evaluating health and maturation of the unborn: the role of the clinical laboratory. Clin Chem 1992;38:1523-1529. Permission granted from Clin Chem.)*

reach 25 IU/L on the first day of their missed period. The peak concentration occurs at about 8 to 10 weeks and is about 100,000 IU/L. Subsequently CG concentrations start to decline in serum and urine, and by the end of the second trimester a 90% reduction from peak concentration has usually occurred. In the first trimester, maternal serum CG is about 96% to 98% intact, 1% to 3% β-subunit, and 0% to 1% α-subunit. During the second trimester, subunit synthesis becomes unbalanced and the serum distribution shifts to 92% to 98% intact, 1% to 7% α-subunit, and 0% to 1% β-subunit.[247] Concentrations are approximately constant during the third trimester, with the predominant species being intact CG. The presence of twins approximately doubles CG concentrations.[328]

COMPLICATIONS OF PREGNANCY

Although most pregnancies progress without problems, complications can arise in the mother, placenta, or fetus.

Abnormal Pregnancies

Conditions arising primarily in the mother include ectopic pregnancy, hyperemesis gravidarum, preeclampsia, HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet counts in association with preeclampsia), liver diseases, Graves' disease, and hemolytic disease of the newborn. The clinician must distinguish abnormal changes in laboratory tests from the normal physiological changes induced by pregnancy (see Table 54-2). Notably, total bilirubin, 5′-nucleotidase, γ-glutamyltransferase (GGT), alanine aminotransferase (ALT), and aspartate aminotransferase (AST) are unchanged in mothers with a normal pregnancy.

Ectopic Pregnancy and Threatened Abortion

When a fertilized egg implants in a location other than the body of the uterus, the condition is called an *ectopic pregnancy.* Most abnormal implantations occur in the fallopian tube but they can also occur in the abdomen, although this is rare. Tubal rupture and hemorrhage are common serious complications of ectopic pregnancy. About 25% of individuals with an ectopic pregnancy have three classic symptoms: lower abdominal pain, vaginal bleeding, and an adnexal mass.[288] Of all individuals with these symptoms, about 15% have an ectopic pregnancy and a smaller percentage have incomplete or complete spontaneous abortion. In the United States from 1990 to 1999, there were 11.8 pregnancy-related deaths per 100,000 live births—6% caused by ectopic pregnancy.[78] Even though the risk of maternal death decreased during this time period, a patient has about a 0.5% chance of dying from an ectopic pregnancy.[142] Management of ectopic pregnancy can be surgical (by laparoscopy) or medical (with intramuscular administration of methotrexate).[16] Early detection and proper management of ectopic pregnancy are the most effective means of preventing maternal morbidity and mortality. Some have suggested that asymptomatic women at high risk for ectopic pregnancy should be screened using ultrasound and laboratory tests.[57]

Ultrasound examination and quantitative measurements of serum CG can be useful in identifying women with ectopic pregnancies or abnormal intrauterine pregnancies. These conditions frequently produce abnormal CG concentrations and slow rates of increase.[48] In addition, progesterone measurements can be helpful either individually or in combination with CG.

Kadar and colleagues[177] reported in 1981 that ultrasonography should detect a gestational sac in the uterus of all patients having CG concentrations greater than 6500 IU/L. They termed this concentration the "discriminatory zone." The threshold has now decreased several times because of improvements in ultrasonographic resolution and the introduction of endovaginal ultrasound. The current cutoff is as low as 1500 IU/L, but has a sensitivity of only 42% and specificity of 81% for the detection of ectopic pregnancy when no gestational sac is found in the uterus.[187] In 1994, Kadar and colleagues[175] concluded that the CG concentration should not be used to predict a gestational sac if the gestational age is known with confidence. The best predictor is an accurate gestational age. Failure to detect a gestational sac by sonography 24 days or more after conception is presumptive evidence of an ectopic pregnancy.

Romero and colleagues[277] reported that in 184 patients with ectopic pregnancies, CG concentrations ranged from 0 to 200,000 IU/L, with a geometric mean of about 1000 IU/L. Concentrations of CG depend on the size and viability of the trophoblastic tissue. In about 1% of patients with an ectopic pregnancy, the CG is undetectable using serum tests capable of measuring concentrations as low as 5 IU/L. Qualitative serum tests with limits of detection of about 50 IU/L can be very useful for rapid determination of pregnancy in this

clinical setting.[197] To distinguish further between the various possibilities, serial testing of CG may be very helpful. In normal intrauterine pregnancy, a rapid increase in CG follows. During the second through fifth weeks, the CG doubles in about 1.5 days. After 5 weeks of gestation, the doubling time gradually lengthens to 2 to 3 days.[263] Before 7 weeks, calculation of the slope of log(CG) versus time in days is useful for identifying normal pregnancies.[176] At least two CG determinations should be obtained from specimens collected 1 to 7 days apart. The log-linear slope, Δlog(CG)/Δ time (in log(IU/L)/day), is greater than 0.11 in the vast majority of normal pregnancies. In cases of ectopic pregnancies or spontaneous abortions, the slope is usually less than 0.11, and the CG concentrations often decrease.

Serum progesterone concentration is often low in mothers with abnormal pregnancies.[269] In a study[98] of asymptomatic women less than 8 weeks from their last menses, a serum progesterone less than 6 ng/mL predicted an abnormal pregnancy outcome with 81% confidence, but the average serum progesterone in nonviable pregnancies was 10 ng/mL. For women with clinical symptoms of abnormal pregnancy, measurement of both CG and progesterone is more predictive of abnormal pregnancy than a single CG measurement. In a large outcome study, 97% of the patients with CG <3000 IU/L and progesterone <12.6 ng/mL had an abnormal pregnancy outcome, whereas those with CG >3000 IU/L or progesterone >12.6 ng/mL had a normal pregnancy.[241] McCord and associates[214] reported that for women at risk for ectopic pregnancy, a progesterone cutoff of 17.5 ng/mL detected 92% of the ectopic cases (clinical sensitivity), but had a very poor clinical specificity of about 14%. They concluded that patients with progesterone greater than 17.5 ng/mL needed no additional laboratory tests. Finally, in symptomatic patients, Stewart and colleagues[304] reported a sensitivity of 99% and specificity of 65% when using the Δlog(CG)/Δtime >0.14 to distinguish normal intrauterine pregnancy from ectopic pregnancy combined with inevitable abortion. A progesterone cutoff above 8 ng/mL had a sensitivity of 81% and a specificity of 88%.

Liver Disease

There are a number of liver disorders unique to pregnancy.[186] These include hyperemesis gravidarum, cholestasis of pregnancy, fatty liver of pregnancy, preeclampsia and eclampsia, and the HELLP syndrome. These disorders must be distinguished from the normal physiological changes of pregnancy (see Table 54-2). Significant changes normally seen in pregnancy include a dilutional decrease in serum albumin and elevation of alkaline phosphatase (from the placenta). Total bilirubin, 5′-nucleotidase, GGT, ALT, and AST are unchanged. Changes in these analytes reflect hepatobiliary disease.

Hyperemesis Gravidarum

Hyperemesis gravidarum is characterized by nausea and vomiting and, in severe cases, dehydration and malnutrition. It typically occurs in the first trimester. When hyperemesis is severe enough to cause dehydration, abnormal liver enzyme values—usually less than four times the upper reference limit—are seen in approximately 50% of patients.[340] Mild hyperbilirubinemia may occur. However, significant liver disease does not occur, and liver biopsy results are normal. Low-birth-weight babies are common, especially for women who develop malnutrition.

Cholestasis of Pregnancy

Cholestasis of pregnancy usually occurs in the third trimester and is manifested clinically by diffuse pruritus and, in 20% to 60% of patients, jaundice. The typical features of cholestasis, including pale stools and dark urine, are present and last until delivery. Women who experience cholestasis while taking oral contraceptives will usually develop cholestasis of pregnancy. Serum bilirubin rarely exceeds 5 mg/dL. Alkaline phosphatase is typically two to four times the upper reference limit. Aminotransferase enzyme concentrations are mildly elevated. There may be an elevated prothrombin time because of vitamin K malabsorption. Although some clinicians order serum bile acids in this setting, this test is rarely necessary for diagnosis. The condition itself is benign, but is associated with an increased risk of premature birth and fetal death. It recurs with subsequent pregnancies.[271]

Fatty Liver of Pregnancy

Fatty liver of pregnancy occurs in 1 in 7000 pregnancies and is characterized by accumulation of microvesicular fat in the liver.[65] Although the exact cause is unknown, this disorder occurs more often in women who have a fetus affected with a mitochondrial fatty acid oxidation disorder, long chain 3-hydroxyacyl-CoA dehydrogenase deficiency (LCHAD).[318] The disease typically occurs at week 37 and is manifested clinically by the rapid onset of malaise, nausea, vomiting, and abdominal pain. Mild elevations in aminotransferase enzyme concentrations occur, with the AST elevation typically greater than the ALT elevation but both less than six times the upper reference limit. The serum bilirubin is usually greater than 6 mg/dL. Life-threatening hypoglycemia may occur.[275] Hyperuricemia, presumably from tissue destruction and renal failure, is characteristic. Liver histology shows acute fatty infiltration with little necrosis or inflammation. The fat is microvesicular and pericentral in the cell, similar to what is seen in Reye's syndrome. If untreated, fulminant hepatic failure with hepatic encephalopathy ensues. Treatment is immediate termination of the pregnancy, at which time rapid recovery usually occurs. Infant and maternal mortality is approximately 20%. Recurrence in subsequent pregnancies is very rare.

Preeclampsia and Eclampsia

Preeclampsia is characterized by hypertension, proteinuria, and edema, usually occurring late in the second trimester or early in the third trimester. The cause is unclear, but research

suggests that increased circulating soluble fms-like tyrosine kinase 1 (sFlt-1) may have a role.[200]

It is related to abnormal endothelial reactivity that leads to intravascular deposition of fibrin with subsequent end-organ damage.[276] Most maternal deaths are due to central nervous system complications, but the liver may also be the target of injury. The injury to the liver is ischemic. Modest elevations in ALT and AST occur, typically 4 to 10 times the upper reference limit. Hepatic complications, including hemorrhage, infarction, and fulminant hepatic failure, may occur and necessitate early delivery.

HELLP Syndrome

The HELLP syndrome occurs in 0.1% of pregnancies. The most prominent features are thrombocytopenia and disseminated intravascular coagulation (DIC). Most cases occur between the 27th and 36th weeks of pregnancy, but it also may occur postpartum. Women typically present with epigastric or right upper quadrant pain, malaise, nausea, vomiting, and headache.[212,282] Jaundice occurs in 5% of patients. Lactate dehydrogenase (LD) concentrations may be very high, and ALT and AST are usually 2 to 10 times upper reference limits. Treatment is delivery. The postpartum management of the patient may require plasmapheresis or organ transplantation. Recurrence rates are 3% to 27%.

Non–Pregnancy-Related Liver Disease in Pregnancy

Pregnancy does not preclude the acquisition or aggravation of non–pregnancy-related liver disease. Thus cholestasis during pregnancy may reflect the presence of hepatotoxicity from drugs, primary biliary cirrhosis, Dubin-Johnson syndrome, or cholelithiasis (see Chapter 47). Abdominal ultrasound, endoscopic retrograde cholangiography, or liver biopsy may be necessary to exclude these conditions.

Viral hepatitis occurs with the same frequency in pregnancy as would be expected in a comparable age group.[280] It is manifested by malaise, nausea, vomiting, dark urine, and mild fever. AST and ALT are virtually always greater than 10 times the upper reference limit and usually greater than 20 times the upper reference limit. The prognosis, with the exception of hepatitis E and herpes simplex, is the same as in nonpregnant women. Hepatitis E, an enteric infection occurring in India, Africa, the Middle East, and Central America, has a mortality rate of 15% to 20% in the pregnant patient.[190] Herpes simplex hepatitis, usually accompanied by oral or vulvar vesicles, has a mortality rate of 43%.[183] Distinguishing features include a mild bilirubin elevation and marked aminotransferase elevations. Liver biopsy is usually required for diagnosis and demonstrates typical intranuclear inclusions and the other usual features of viral hepatitis. Antiviral therapy greatly improves the prognosis.

Women who acquire hepatitis B late in pregnancy or who are chronic carriers are likely to transmit the disease to their babies. This is especially so if the mother is HBeAg positive (see Chapter 47). The outcome in the infant varies from fulminant hepatitis (rare and usually in anti-HBe-positive mothers) to mild hepatitis to chronic hepatitis (the usual outcome in 90% of chronically infected woman). All pregnant women should be screened for hepatitis B with HBsAg.[7] If positive, their babies should be immunized with hepatitis B immune globulin and hepatitis B vaccine. Babies born to hepatitis C–positive mothers usually have the passively transmitted antibody for several months, but transmission of active hepatitis is unusual.[311] Because there is no known treatment for the newborn, screening is not recommended for hepatitis C virus infection.

Differential Diagnosis

It is often difficult to distinguish the various liver diseases of pregnancy from each other and from naturally occurring liver diseases. Acute fatty liver is suggested when nausea, vomiting, and abdominal pain are followed by jaundice, and encephalopathy occurs in the presence of a small or normal-sized liver. The white blood cell count is usually elevated above 15,000 cells/μL and ALT levels are typically four to six times the upper reference limit. Hypoalbuminemia, hyperuricemia, hypoglycemia, and DIC are typical. Hepatic ultrasound and computed tomography (CT) will usually demonstrate fatty liver when present. In preeclampsia and the HELLP syndrome, the liver is usually enlarged, ALT levels are usually lower, and bilirubin levels are mildly elevated or normal. Hyperuricemia is uncommon. Marked elevations in aminotransferase enzyme levels suggest hepatic infarction or viral hepatitis. Liver biopsy may be needed to differentiate non–pregnancy-related causes of liver disease, but should not be used to differentiate acute fatty liver from preeclampsia or HELLP syndrome because the treatment is the same for all of these conditions—delivery of the infant.[219]

Effect of Pregnancy on Preexisting Liver Disease

Conception and full-term parturition do not usually occur in women who have cirrhosis. However, liver disease is not a reason for termination. The hypervolemia associated with pregnancy may aggravate cirrhosis and predispose to bleeding from esophageal varices.[49]

Autoimmune chronic hepatitis is usually associated with amenorrhea, but pregnancy may occur after treatment to remission with corticosteroids. The steroids should be continued during the pregnancy. Pregnancy should be avoided in patients being treated with azathioprine.

Neonatal Graves' Disease

The fetal thyroid-pituitary axis functions independently from the mother's axis in most cases. However, if the mother has preexisting Graves' disease (see Chapter 52), her autoantibodies can cross the placenta and stimulate the fetal thyroid gland. Thus the fetus can develop hyperthyroidism. Measurement of thyrotropin-binding inhibitory immunoglobulins (TBII) is useful for assessing risk of fetal or neonatal Graves' disease.

Hemolytic Disease of the Newborn

Hemolytic disease of the newborn (HDN) is a fetal hemolytic disorder caused by maternal antibodies directed against antigen on fetal erythrocytes. Commonly used synonyms for this disorder are *isoimmunization disease, Rh isoimmune disease, Rh disease,* or *D isoimmunization.* Any of a large number of erythrocyte surface antigens Rh(CDE), A, B, Kell, Duffy, Kidd, and others may be responsible for isoimmune hemolysis. When severe, the disorder is known as *erythroblastosis fetalis* and is life threatening to fetus and newborn. The most common cause of severe disease is sensitization of a D-negative woman. The amount of bilirubin in the amniotic fluid is useful for determining the severity of the disease. Pioneering work by Bevis[37-40] uncovered the association between amniotic fluid bilirubin and D isoimmunization. Liley[201] extended this work by noting an association between gestational age, severity of the disease, and bilirubin concentration.

Rh Blood Groups

Two genes, *RhD and RhCE,* encode for erythrocyte membrane proteins that are antigenic. Both are located on chromosome 1p about 30 kb apart. Approximately 15% of Caucasians, 5% of Africans, and less than 1% of Asians are RhD-negative. The most prevalent RhD-negative allele appears to be a deletion.[27] Exon 5 of *RhCE* has two common polymorphisms producing *E* or *e* antigen. Exon 2 of *RhCE* has two common polymorphisms producing *C* or *c* antigen.

Etiology

Sensitization, or production of a maternal antibody, may occur in response to blood transfusion or a pregnancy in which the fetus has a blood cell antigen that the mother lacks. Although the fetal and maternal blood compartments are generally considered to be separate during normal gestation, small numbers of fetal erythrocytes are continually gaining access to the maternal circulation. This antigenic challenge is sufficient in some women to provoke an antibody response. Substantially larger antigenic exposures may result from those disruptions in the integrity of the fetal compartment that accompany spontaneous or induced abortion, ectopic pregnancy, or delivery of an infant. The larger the fetomaternal hemorrhage, the more likely it is that the mother will respond to the challenge by developing an antibody. Other antigens of the Rh system—C, c, E, e—may stimulate antibody formation, but appear to be less than one one thousandth as potent.

The IgG produced is actively transported across the placenta into the fetus. When a sensitized woman is pregnant with an RhD-positive fetus, the antibodies cause destruction of the fetal erythrocytes. Furthermore, during pregnancy or at the time of delivery, repeat exposure to RhD-positive erythrocytes causes an augmented response, resulting in higher antibody titers. This augmented response is responsible for the frequent observation that subsequent pregnancies are frequently more severely affected than earlier ones.

The pathophysiology of isoimmune hemolysis is the same for all antigens. The differences in severity of disease are due to differences in the expression of the antigen on the surface of the cells, the intrinsic immunogenicity of the antigen, and peculiarities of the immune response of the mother. Destruction of the fetal erythrocytes, which is the central problem, produces several other problems. Fetal anemia imposes an extra burden on the fetal heart to provide adequate oxygen supply to fetal tissues. Anemia stimulates the fetal marrow and extramedullary erythropoiesis in the liver and spleen to replace the destroyed erythrocytes. Extramedullary erythropoiesis destroys hepatocytes and leads to decreased production of serum albumin and decreased oncotic pressure in the intravascular space.

These changes, when severe, lead to congestive heart failure and generalized fetal edema, with ascites and pleural and pericardial effusions. When the fetal condition has deteriorated to this degree, it is referred to as *hydrops fetalis* and carries a very grave prognosis. The edema and effusions are readily observable by ultrasonographic examination. When these changes are observed and there is no therapeutic intervention, intrauterine demise follows in a relatively short time.

If a fetus survives, the newborn will encounter a number of problems. In utero, the placenta and mother perform the functions of respiration and removal of bilirubinoid pigments resulting from hemolysis. Newborns must assume these functions for themselves in the presence of hydrops. The lungs are edematous, and pleural effusions and ascites physically restrict their ability to expand. The damaged liver is unable to conjugate and excrete bilirubin adequately. When bilirubin accumulates in the blood to excessive concentrations, it passes through the blood-brain barrier to deposit in the brain and destroy brain cells. This form of brain damage is termed *kernicterus.* Thus, although kernicterus was not a concern in the fetus, it is a significant concern in these sick newborns. A severely erythroblastotic baby can be one of the most challenging problems in a neonatal intensive care unit.

Prophylaxis

An anti-RhD immune globulin, RhoGAM (Ortho Clinical Diagnotics, Raritan, N.J.), has been used in the United States since 1968,[46] and other similar products were introduced in 1971 and later. A 300 µg dose is administered intramuscularly to a mother potentially exposed to 15 mL or less of RhD-positive fetal erythrocytes following abortion, fetomaternal hemorrhage, amniocentesis, chorionic villi sampling, or delivery.[13] Use of RhD immunoglobulin has been responsible for the dramatic reduction in the incidence of HDN. In addition to recognized fetomaternal hemorrhage, undetected transplacental fetomaternal bleeding during an apparently normal pregnancy can lead to antepartum sensitization. This would not be prevented by immediate postpartum administration of RhD immunoglobulin; therefore antepartum administration at 28 weeks of gestation is recommended for RhD-negative women. Despite this

immune prophylaxis, a small number of sensitized pregnancies continue to occur.

Clinical Management of Sensitized Mothers

To identify sensitized women, an alloantibody screen is performed at the first prenatal visit.[222] If an antibody to an erythrocyte antigen is identified, the titer is determined.[9] The critical anti-RhD titer depends on the laboratory, usually 1:8 to 1:32, although studies of critical titer are quite disparate.[144] For all sensitized women, the paternal erythrocyte phenotype is determined. If the father is RhD-negative, then no follow-up studies are required. If he is D-positive, then his Rh phenotypic zygosity is estimated (genotyping will most likely be used in the future). If the paternal Rh genotype is likely heterozygous for D, then the Rh D status of the fetus needs to be determined.[222] Amniotic fluid is collected by amniocentesis for fetal RhD genotyping by polymerase chain reaction (PCR). To guard against a false negative caused by a paternal RhD gene rearrangement (occurring in about 1.5% of Caucasians), the father can also be genotyped. A frequent occurrence in those of African ancestry is an RhD pseudogene; the patient is RhD-negative by serology, but RhD-positive on genotype. If the fetus is RhD-genotype-positive, the mother (who is RhD-negative serologically) should be tested for RhD genotype. In the United Kingdom, laboratories have begun to offer fetal Rh genotyping using cell-free fetal DNA that circulates in maternal blood (see Chapter 36).[123]

For sensitized mothers with an at-risk fetus, serial titers are performed on maternal serum every month until 24 weeks gestation, then every 2 weeks thereafter. If a critical titer anti-D is detected, then ultrasound Doppler measurements are used to determine the peak velocity of blood flow in the fetal middle cerebral artery. Higher velocity is a strong indicator of fetal anemia. In addition, amniocentesis is performed to assess the bilirubin concentration in amniotic fluid.

Liley noted that the degree of hemolysis in sensitized pregnancies could be assessed by measuring the absorbance of bilirubinoid pigments in amniotic fluid and classifying the results into three zones based on gestational age.[201] The procedure was originally called ΔOD_{450},[201] a term still used by most clinicians. The preferred clinical chemistry term is ΔA_{450}. This method is described later in this chapter in the section entitled Laboratory Tests. Serial testing is indicated every 10 to 14 days. If the ΔA_{450} rises or plateaus at about the 80th percentile of zone 2 on the Liley curve, fetal blood sampling is indicated. Ultrasound-guided umbilical blood sampling is performed to determine fetal blood type, hematocrit, antibody screen, reticulocyte count, and total bilirubin. Intrauterine intravascular blood transfusion can be performed if indicated. If fetal pulmonary maturation has occurred (usually 35 weeks or greater), delivery is indicated.

TROPHOBLASTIC DISEASE

Serum CG determinations are very useful for monitoring patients with germ cell–derived neoplasms or other CG-producing tumors, such as lung carcinoma. The use of CG in these diseases is discussed in Chapter 23.

FETAL ANOMALIES

Open neural tube defects, Down syndrome, and trisomy 18 (discussed separately below) are fetal anomalies that are partially detectable by maternal serum screening. However, because of the large number of pregnancies screened, and the interest in other fetal conditions and their possible association with abnormal maternal serum analyte concentrations, a wealth of associations between rarer conditions and screening results has been published. These findings are never diagnostic and are reported rarely by the screening laboratory. In certain circumstances, however, the healthcare provider may determine a need for more extensive medical evaluation.

Neural Tube Defects

Neural tube defects are serious abnormalities that occur early in embryonic development. By 19 days after fertilization, the area that is to form the central nervous system (brain and spinal cord) has differentiated into a plate of cells. The flat plate then rolls up, and its edges fuse into a hollow neural tube that drops into the embryo to develop just underneath what will become the skin of the back. Neural tube formation is normally complete 4 weeks after fertilization. Failure of neural tube fusion leads to permanent developmental defects of the brain or spinal cord or both. These defects are called *anencephaly*, *meningomyelocele* (which is commonly called *spina bifida*), and *encephalocele*. Although there are many heterogeneous causes, about 90% fall into the classification of multifactorial inheritance.[165] Folic acid deficiency is clearly associated with increased frequency of neural tube closure defects.[326] The cause in these cases may be derangement of homocysteine metabolism caused by the folate deficiency.[302] Estimates attribute 70% or more of all neural tube defects to folate deficiency.[334] Since 1997, grain products in the United States and Canada have been fortified with 140 μg folic acid/100 g,[124] but the amount added is unlikely to be sufficient to reduce the birth prevalence by more than about 30%, the reduction that is commonly reported in observational trials.[253] Organizations such as the March of Dimes are conducting vigorous campaigns to educate women of the need for folic acid supplementation before becoming pregnant, as recommended by the Centers for Disease Control and Prevention.[67] Most vitamin supplements contain the 400 μg of folic acid recommended daily by authorities.[226]

The birth prevalence of open neural tube defects varies with factors such as geographic location (higher in the Eastern United States, lower in the West), race (lower in African-Americans), ethnicity (higher in Scotch-Irish), family history (higher with prior births of affected individuals),[83] and maternal weight (higher in obese women).[290,339] An average figure for the United States is 1 open neural tube defect per 1000 pregnancies (about 1 in 2000 for each indi-

Figure 54-4 The relationship of maternal age and the risk of having a pregnancy affected with Down syndrome. *Dotted line,* Second trimester risk; *solid line,* term risk. *Vertical line* at age 35 is the cutoff used for selecting women at increased risk based on maternal age.

vidual defect). Almost all cases of anencephaly and about 95% of meningomyeloceles are open, with no overlying skin, and therefore are in direct communication with the amniotic fluid. Thus the fetal serum proteins normally present in amniotic fluid at low concentrations gain access in large quantities to the amniotic fluid. The elevated amniotic fluid AFP concentration leads to increased amounts in the maternal circulation. Only open neural tube defects are detected by maternal serum AFP screening, and approximately 90% of these can be detected using maternal serum AFP testing.[330]

Down Syndrome

Down syndrome is the most common serious disorder of the autosomal chromosomes, occurring in 1 in 800 live births. An extra copy of the long arm region q22.1 to q22.3 of chromosome 21 results in a phenotype consisting of moderate to severe mental retardation, hypotonia, congenital heart defects, and flat facial profile. The autosome is the smallest chromosome, making up about 1.7% of the human genome. Most often an affected child has three copies of chromosome 21 (i.e., trisomy 21), but 5% of cases are caused by translocations and 1% of cases are mosaics. The risk increases slowly up to age 30 and then steadily increases as maternal age advances (see Figure 54-4).[168] At 25 years of age, the risk at birth is about 1 in 1000; at age 40 it is 1 in 90.

Trisomy 18

Trisomy 18 (Edwards syndrome) is caused by a nondisjunction event during meiosis that results in a fetus having an extra copy of chromosome 18. Although it occurs in only 1 in 8000 births, it is probably the most common chromosome defect at the time of conception. The dramatic change in prevalence is due to the very high fetal loss rate both before 8 weeks (~80%) and during the second and third trimesters (~70%). Approximately 25% of affected fetuses have meningomyelocele (spina bifida) or omphalocele. There is a high cesarean section rate for undiagnosed cases.[249] Following birth, half of the infants die within the first 5 days and 90% die within 100 days.[64]

Preterm Delivery

The leading cause of neonatal morbidity and mortality in the United States is preterm delivery, with 300,000 to 500,000 cases each year.[5] Infants born before 37 weeks gestation often develop *respiratory distress syndrome* (RDS) and are usually of low birth weight (<2500 g). Some are of very low birth weight (<1500 g). According to the National Center for Health Statistics,[228] in 1993 7.2% of all U.S. live-born infants were low birth weight and 1.3% were very low birth weight. Most of these infants will spend time in intensive care units at a cost of up to $3500 per day.

The cause of preterm labor is unknown, but recent evidence in a mouse model indicates that a maternal serum surfactant protein, SP-A, may trigger labor.[82] Fetal fibronectin and cervical ultrasound have proven value for evaluating patients suspected of having preterm labor. The fetal fibronectin test is described later in the section entitled Laboratory Tests. Use of salivary estriol,[161] corticotropin-releasing hormone,[199] and interleukin-6[140] for preterm labor prediction is being investigated.

Fetal Lung Maturity

RDS, also called *hyaline membrane disease,* is the most common critical problem encountered in clinical management of preterm newborns. The worldwide incidence of RDS is 1% of live births and 10% to 15% of live preterm births (<37 weeks or <2500 g).[232] The risk of RDS is affected strongly by the gestational age at the time of birth: 1% at 37 weeks, 20% at 34 weeks, and 60% at 29 weeks.[120] In 2000 RDS killed just over 1000 infants in the United States.[220] Affected infants require supplemental oxygen and mechanical ventilation to remain properly oxygenated. The disorder is caused by a deficiency of *pulmonary surfactant.* In normal lungs, surfactant coats the alveolar epithelium and responds to alveolar volume changes by reducing the surface tension in the alveolar wall during expiration. When the quantity of surfactant is deficient, many of the alveoli collapse on expiration and thereby overinflate the remaining airways. This process is known as *focal atelectasis.* The lungs become progressively noncompliant, and blood flowing through the capillary beds of collapsed alveoli fails to oxygenate. During the first few hours of life, affected infants develop tachypnea with or without cyanosis, nasal flaring, expiratory grunting, and intercostal retractions. The disease exacerbates during the next few days and is usually worse on the third or fourth day of life. Infants at risk for developing RDS can be treated with intratracheal administration of exogenous surfactant immediately at birth.[157]

Very rarely, respiratory distress in a term newborn can be caused by a mutation in the gene encoding for SP-B.[238] This condition, termed congenital alveolar proteinosis, is often

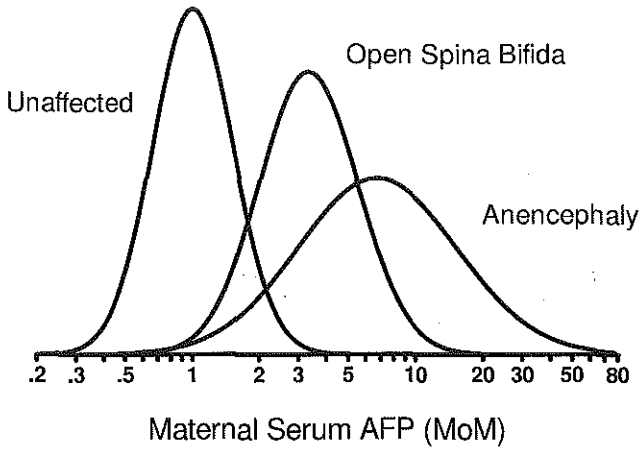

Figure 54-5 Distribution of maternal serum alpha fetoprotein (AFP) measurements in unaffected pregnancies, and pregnancies affected with open spina bifida or anencephaly.

fatal. There is a significant derangement in lamellar body production in these cases. A study of the genetic variation suggests that there may be mild, nonfatal cases of this disorder.[106]

MATERNAL SERUM SCREENING FOR FETAL DEFECTS

In the early 1970s, Brock and colleagues demonstrated increased AFP concentrations in amniotic fluid of mothers carrying fetuses affected with an open neural tube defect (e.g., anencephaly, open spina bifida).[52] Subsequently, it was shown that AFP concentrations were increased in maternal serum (in the second trimester) as well.[50] The concentrations in serum in affected and unaffected pregnancies overlapped considerably, however, indicating that maternal serum AFP would be useful only as an initial screening test to identify women at high risk for having an affected fetus (Figure 54-5). These women would then need to be referred for diagnostic procedures (e.g., high resolution ultrasound and, if indicated, amniocentesis for measurement of AFP and acetylcholinesterase in amniotic fluid) to determine if the fetus had an open neural tube defect. A large collaborative study conducted in the United Kingdom in 1977 showed that maternal serum AFP screening for open neural tube defects in the second trimester of pregnancy was feasible, and the final report provided estimates of screening performance in terms of detection and false-positive rates.[330] A family history of neural tube defects in either parent increases the risk that the fetus is affected by fivefold to fifteenfold, but more than 90% of all infants with neural tube defects are born to unsuspecting parents who have no recognized risk factor for the disorder.[130,316] Maternal serum AFP testing thus provided a screening method available to all women to identify pregnancies at high risk or to estimate the numerical risk of having a fetus with an open neural tube defect.[329] In the 1980s, the use of maternal serum AFP to screen for open neural tube defects became a standard of care in the United States. The American College of Obstetricians and Gynecologists,[10,14] the American Society of Human Genetics,[15] and the American Academy of Pediatrics[3] have issued official statements supporting its use.

In 1984, a major expansion of biochemical prenatal screening became possible when an association between second trimester maternal serum AFP and fetal Down syndrome was reported.[217] Maternal serum AFP concentrations are about 25% lower in Down syndrome than in unaffected pregnancies. Significantly the association was found to be independent of maternal age.[91] Before this discovery, the only available screening test for Down syndrome involved asking a woman her age. If she would be 35 years or older at the time of delivery, she would be offered amniocentesis and fetal karyotyping. Down syndrome screening using maternal age is based on the well-documented increase in risk for having a baby with Down syndrome as maternal age increases (see Figure 54-3). At the time, about 20% of Down syndrome cases occurred in the 5% of women who were 35 years of age or older at the time of delivery. The independence of maternal serum AFP measurements and maternal age established that it was possible to offer a screening method to younger women, in whom most cases of Down syndrome occur. Maternal serum AFP screening for Down syndrome also introduced the concept of using risk, rather than analyte concentration, as the screening variable for identifying high-risk women.[91] Subsequently a large collaborative study established the effectiveness of maternal serum AFP screening in younger women.[235]

The discovery that a protein produced in pregnancy could be altered in the presence of a fetal chromosomal defect stimulated a search for other substances in pregnancy serum that would have predictive value. Of the many that were examined, two emerged as sufficiently discriminatory and independent to be useful additions in screening for Down syndrome in the second trimester. Unconjugated estriol (uE_3),[61] a product of the fetoplacental unit, is also about 25% lower in pregnancies with Down syndrome. In contrast, concentrations of CG were found to be about twice as high.[44] In 1988, a method was proposed for combining maternal age with measurements of these three analytes (the triple test) into a single Down syndrome risk estimate.[331] As with AFP screening, risk, rather than the analyte values themselves, is the screening variable. The triple test was projected to detect 60% of Down syndrome pregnancies by identifying 5% of all pregnant women as having a screen-positive test result (performance based on pregnancies being dated via LMP). The utility of the triple test was confirmed in 1992 by two intervention trials.[149,259] A fourth analyte, DIA, appears to be a useful addition to the triple test, increasing the detection rate by 8% to 10%.[154] This "quadruple test" is becoming more common and the results of two intervention trials confirm its performance advantage.[31,336] A recent external proficiency testing survey conducted by the Foundation for Blood Research and the College of American Pathologists

found that approximately 25% of participating laboratories now offer the quadruple test.[81] Other combinations of second trimester screening tests have been advocated,[210,333] but have not received wide acceptance.

A further expansion of prenatal screening was found to be possible with the discovery that fetal trisomy 18 has a distinctive triple-test pattern that is different from the Down syndrome pattern.[62] In trisomy 18 pregnancies, the AFP and uE_3 concentrations are low, but the CG concentrations are also very low. This is in contrast to Down syndrome, in which the CG measurements are high. Thus few trisomy 18 pregnancies are likely to receive high Down syndrome risk estimates. The initial report[62] included an algorithm that used fixed cutoffs to identify women at high risk of fetal trisomy 18; that algorithm was subsequently validated in an intervention trial.[251] Subsequently, an improved method for trisomy 18 screening was published that used risk as the screening variable as had become standard practice for Down syndrome.[32,122,249]

Clinical Application of Prenatal Screening

Before 2003, most obstetricians offered amniocentesis for fetal karyotype determination to all mothers who would be 35 years of age or older at the time of birth. However, the risk for Down syndrome calculated using biochemical tests is more accurate than the use of maternal age alone, and it is now common practice to offer maternal serum screening to women of all ages. It may be prudent, however, to continue to offer the option of amniocentesis to women age 35 and older, because amniocentesis is still considered by some to be the standard of care. In recent years, the proportion of pregnant women who are 35 years of age or older increased from 5% to 14% of the total, and about half (up from 20%) of all Down syndrome cases occur in this group.[184] If all of these women were to undergo amniocentesis, 1 in every 180 would be found to have a Down syndrome pregnancy. In contrast, the second trimester quadruple test can detect 75% to 80% of Down syndrome cases with only 5% to 6% of women having a positive screening test when the screening is applied to pregnant women of all ages.[154] Approximately 1 in every 50 mothers who are classified as being at high risk will be found to have a fetus with Down syndrome.[149]

Maternal serum screening using the triple test sometimes produces a pattern of low results for AFP, CG, and uE_3.[62] Using an algorithm specifically designed to assign patient-specific risk for trisomy 18, 60% of affected pregnancies can be detected with a false-positive rate of about 0.3%.[249] Among women with a second trimester trisomy 18 risk of 1:100 or greater, 1 in 16 will have a pregnancy affected with trisomy 18.

Multiple of the Median

Understanding the published literature and clinical screening applications requires an understanding of the statistic used to normalize analyte values, the multiple of the median (MoM). The initial step in calculating a MoM is to develop a set of median values for each week (or day) of gestation using the laboratory's own assay values measured on the population to be screened. Individual test results are then expressed as MoM by dividing each individual test result by the median for the relevant gestational week. This convention was originally developed as a means of taking into account the large differences among centers in AFP assay values seen in the 1977 U.K. collaborative study.[330] Converting assay results to MoM units also compensates for the steadily rising AFP concentration in maternal serum during the second trimester and the corresponding decrease in AFP values in amniotic fluid, allowing a single statistic to be used for expressing results. Subsequently, it was found that MoM values could also be adjusted to take into account other factors (e.g., maternal weight and maternal race) that materially affect analyte values.[151] The MoM is now universally used as a common currency for converting analyte values into an interpretative unit and is also the starting point for calculating risks for neural tube defects, Down syndrome, and trisomy 18.[249,329,331]

Neural Tube Defect Screening Using Maternal Serum Alpha Fetoprotein

Population-based prenatal screening began in the late 1970s with the use of maternal serum AFP measurements to identify women at increased risk of carrying a fetus with an open neural tube defect.[330] Although a patient-specific risk can be used when screening for open neural tube defects,[329] nearly all laboratories define a screen-positive result as AFP at or above a fixed MoM cutoff. Optimal screening is between 16 and 18 completed weeks of gestation, a time when the distributions of results for affected and unaffected pregnancies are maximally different and there is adequate time for follow-up studies. Screening at 15 weeks is acceptable, but at 14 weeks or earlier, screening for open neural tube defects is difficult to justify.[330,334] The two most commonly used AFP MoM cutoffs in the United States are 2.0 and 2.5 MoM, yielding initial screen-positive rates of 3% to 5%, and 1% to 3%, respectively. The observed rates are more likely to be at the lower end of the cited ranges if many pregnancies are dated by ultrasound. This improvement is a result of the finding that increased AFP values attributable to underestimated gestational age, fetal demise, and twin gestation will usually have been identified. The lower initial positive rate at 2.5 MoM is associated with a reduced detection rate for open spina bifida: 70% to 75% as compared with 80% to 85% at 2.0 MoM.[94,330] A recent survey found that 52% of laboratories in the United States use a 2.5 MoM cutoff, 30% use a 2.0 MoM, and the remainder use a cutoff in between these two values.[60]

Follow-up Testing for Women With Screen-Positive Results

Women who have a positive screening test result for open neural tube defects are usually referred for genetic counsel-

ing and further testing. Some programs may ask for a second sample for moderately elevated results (2.0 to 3.0 MoM) to repeat the test. If the result for the second AFP test is not elevated, the woman is considered to be screen-negative. If the result is still elevated, the patient is referred for further testing. After genetic counseling to explain the test results, to provide more information about the disorder, and to describe the risks and benefits of further testing, a low resolution ultrasound examination may be offered as a way to verify gestational age and to identify other possible reasons for the increased AFP test results (e.g., recent fetal demise and twins). Patients having an unexplained high maternal serum AFP result can then be offered amniocentesis for measurement of amniotic fluid AFP and acetylcholinesterase (AChE), high resolution ultrasound, or both.

Compared with maternal serum, amniotic fluid AFP concentrations in pregnancies affected with open neural tube defects are far more separated from unaffected pregnancies.[327] However, amniotic fluid AFP measurements are not by themselves diagnostic because of false-positive results. If the amniotic fluid is contaminated with even a small amount of fetal blood, as many as 2% to 3% of the results can be falsely positive.[327] All abnormal amniotic fluid AFP results must be confirmed by measurement of amniotic fluid AChE. The combination of amniotic fluid AFP and AChE is virtually diagnostic for an open neural tube defect.[270,327]

High resolution ultrasound can almost always confirm a chemical diagnosis of a neural tube defect. Anencephaly is readily identifiable, and ultrasound diagnosis of open spina bifida is considerably enhanced by the presence of two cranial signs (fruit signs) resulting from the Arnold-Chiari malformation associated with this defect.[104,236] The first sign is a "pinched" skull in the frontal region resulting in a "lemon" shape compared with the normal egg shape. The second sign is a reduction in the transverse diameter of the cerebellum leading to the two cerebellar hemispheres assuming a bow shape, the "banana sign." Ultrasound diagnosis of open neural tube defects is now so reliable that it is often used for diagnosis in women with elevated maternal serum AFP without waiting for amniotic fluid measurements.

Down Syndrome Screening Using Multiple Biochemical Tests

The most common combination of second trimester maternal serum biochemical tests used to screen for Down syndrome in the United States is the triple test (maternal age in combination with AFP, uE_3, and CG measurements).[80] Many laboratories are offering DIA measurements to form the quadruple test.[81] Measurements of each analyte are made on a single serum sample (the same one used for open neural tube defect screening) and the results in mass units are converted to MoM for the appropriate week (or day) of gestation. This MoM value is then adjusted for other variables, such as maternal weight and race. Patient-specific Down syndrome risks are then calculated using the adjusted MoM values along with the woman's maternal age at delivery employing an algorithm that uses overlapping multivariate Gaussian distributions. The prior odds based on age are then multiplied by this likelihood ratio to assign the final patient-specific Down syndrome risk. This final risk, rather than the analyte values themselves, is the screening variable upon which clinical decisions are made.

The detection and false-positive rates achievable depend on many factors including (1) the test combination chosen, (2) the risk cutoff chosen, (3) the method of dating used to establish gestational age, and (4) the maternal ages of the women being tested. Table 54-3 summarizes the impact of these factors in a hypothetical cohort of women having the maternal age distribution found in the United States in 2000.[154] In the United States, many laboratories use the triple test (AFP, uE_3, CG) and a cutoff equivalent to the risk of a 35-year-old woman (1:270 in the second trimester or 1:350 at term). At this risk cutoff and with use of the date of the

TABLE 54-3 Estimated Down Syndrome Detection Rates (DR), False-Positive Rates (FPR), and Odds of Being Affected Given a Positive Result (OAPR) at Three Risk Cutoff Values for Selected Combinations of Maternal Serum Marker and Two Methods of Dating

	AFP, uE_3, CG, DIA	75	78	5.0	5.1	48	48

LMP, Gestation age estimated from last menstrual period; *US*, gestational age estimated from ultrasound measurements; *AFP*, alpha fetoprotein; *uE_3*, unconjugated estriol; *CG*, chorionic gonadotropin; *DIA*, dimeric inhibin A.

LMP to estimate gestational age, the triple test yields an initial positive rate of 6.6% and a detection rate of 70%. If pregnancies are dated by ultrasound, the detection rate increases to 74% and the screen-positive rate declines slightly to 6.5%. Some laboratories choose instead a risk cutoff to obtain an initial positive rate of about 5% (4.6% in the table with LMP dating). This lower rate occurs at a second trimester screening cutoff that corresponds to a 1:190 risk (1:250 risk at term) and is associated with a detection rate of 65%. If DIA measurements are added to the triple test, the detection rate increases to about 78%, and the initial positive rate decreases to 5.1% (LMP dating at a risk cutoff of a 35-year-old woman). The table demonstrates how the choices of test combination and risk cutoff affect the detection and screen-positive rates.

Follow-up Testing for Women With Screen-Positive Results

Women who have a positive screening test result for Down syndrome are usually referred for genetic counseling and further testing. After counseling, a low-resolution ultrasound examination may be offered as a way to verify gestational age and to identify other possible reasons for the positive test result. One of the most common reasons for increased Down syndrome risk is overestimated gestational age. Up to one third of women with positive Down syndrome screening results who are dated by the last menstrual period will be found to be too early in their pregnancies for reliable screening (less than 15 weeks) or reclassified as low risk after ultrasound revision of gestational age.[149] Women who are still at increased risk after the ultrasound examination should be offered amniocentesis to obtain fetal cells for karyotyping. Although some second trimester ultrasound findings are associated with Down syndrome (e.g., nuchal fold and shortened femur and humeral length), these findings are not diagnostic.[296] The only way to diagnose Down syndrome is via fetal karyotype. However, the benefits of accurately diagnosing a chromosome abnormality early in gestation must be weighed against the potential for harming a normal fetus during amniocentesis. This invasive procedure carries a small but real risk of harming the fetus or causing spontaneous abortion. Even amniocentesis performed by an experienced obstetrician using ultrasonography for guidance has a procedure-related rate of fetal loss of about 1 in 200.[297] Given that about 1 in 50 women with an unexplained screen-positive test result (high risk) will have a fetus with a chromosome abnormality, the offer of the invasive procedure is reasonable.

Trisomy 18 Screening Using Multiple Tests

Trisomy 18 is the least common of the three disorders considered for second trimester maternal serum screening. It is also the one that is least compatible with life. For these reasons, justification of a screening program exclusively devoted to the prenatal identification of trisomy 18 is difficult. However, given that the serum analytes are already being measured to screen for Down syndrome and open neural tube defects, adding an additional interpretation of these analytes to quantify the risk of fetal trisomy 18 might be warranted. However, since the birth prevalence of trisomy 18 is one tenth that of Down syndrome,[249] the percentage of women identified as screen-positive must be correspondingly lower than that for Down syndrome. A risk-based algorithm showed that at a second trimester risk cutoff of 1:100, 60% of trisomy 18 pregnancies could be identified, with about 0.5% of women having an initial positive screen. This algorithm will identify 1 trisomy 18 fetus for every 16 amniocenteses that result from the program.[249] Risk for trisomy 18 is also based on multivariate overlapping Gaussian distributions, with the appropriate parameters being used for the affected population. Women with a risk higher than a specified cutoff are referred for genetic counseling and further testing.

Follow-up Testing for Women With Screen-Positive Results

In contrast to the screening protocols for open neural tube defects and Down syndrome, a dating ultrasound is not recommended as the first step after a finding of increased risk of trisomy 18. The trisomy 18 pattern of low AFP, low uE_3, and low CG is not consistent with incorrect gestational dating, and the direct offer of amniocentesis is warranted.[122,251] A high proportion of fetuses with trisomy 18 will have abnormal but nondiagnostic second trimester ultrasound findings (e.g., heart defects and clenched fists).[28]

Establishing Assay-Specific and Population-Specific Median Values

One of the most important responsibilities of the prenatal screening laboratory is to establish kit-specific and population-specific median values for each analyte used in screening or to show that median values obtained from another source are appropriate. Relatively small errors in median values can have a disproportionate impact on both the accuracy of the calculated risk and the number of women identified as screen-positive. Values measured on the same patients and the same proficiency testing samples can differ among methods by 5% to 200% depending on the analyte measured.[81] Median values are therefore not directly transferable between reagent sets from different methods. Median values can also differ among laboratories even when the same methodology is employed. This difference is caused by such factors as the method and reliability of gestational dating, race, maternal weight, and even apparently subtle differences in assay instrumentation, or changes in manufacturer's lot numbers of reagents or calibrators.[116]

Median values must be routinely monitored and updated as necessary. Median values provided in package inserts for AFP are not acceptable for many of the reasons given above. It has been recommended that median values be established using at least 100 values for 15 through 20 weeks of gestation. In practice, however, obtaining 100 serum samples for

each gestational week is very difficult even for large laboratories, because most specimens are now routinely collected between 16 and 18 weeks gestation (the optimum time for open neural tube defect screening). Given these constraints, the following strategies are recommended for obtaining reliable median values, categorized according to whether a laboratory is implementing a screening test for the first time or is updating an existing set of median values.

Two alternatives are available when a laboratory is establishing median values for the first time. The optimal method is to obtain measurements on 300 to 500 patient specimens using the assay selected for screening. Establishing that all of these samples come from unaffected singleton pregnancies is not necessary because the prevalence of conditions that produce abnormal values (e.g., twins, fetal demise, and open fetal defects) is small and will have minimal impact.[150] The data are used to derive median values for each completed week of gestation. Appropriate weighted regression analysis can then be used to fit the observed data. The regression equation is used to predict "smoothed" medians for each week of gestation. Measurements of AFP and uE_3 increase by a constant proportion—about 10% to 15% per week for AFP and 20% to 25% per week for uE_3 measurements. A log-linear model best fits this relationship (i.e., the log of the measurements [y-axis] is regressed against gestational age [x-axis]). Usually the median value is found at each completed week and regressed against the average gestational age for that week. This technique helps reduce the effect of outliers. Weighting takes into account the reliability of these summary estimates and is usually based on the square root of the number of samples observed at each week. The regression model for CG versus gestational age fits an exponential model similar to that used for radioactive decay. Measurements of DIA are relatively flat, but experience has shown that a quadratic model fits the data well, with a minimum found between 16 and 18 weeks gestation. Table 54-4 provides data for these four tests along with the weighted regression equation and resulting smoothed medians. The AFP and uE_3 medians increase 11% and 23% per week, respectively. Figures 54-6 to 54-9 are graphical representations of the data in Table 54-4, and the legends contain the respective median regression equation. Although laboratories cannot use these medians to interpret their own assay results, they can use the observed median concentrations for each analyte (plus weeks and N) to verify their ability to compute regressed median concentrations.

Figure 54-10 shows the relative gestational age effects on the four tests. Each test is assigned a 100% relative value for the median at 15 completed weeks of gestation. If the median values increase, the line will have a positive slope. The test that is least influenced by gestational age is DIA. The

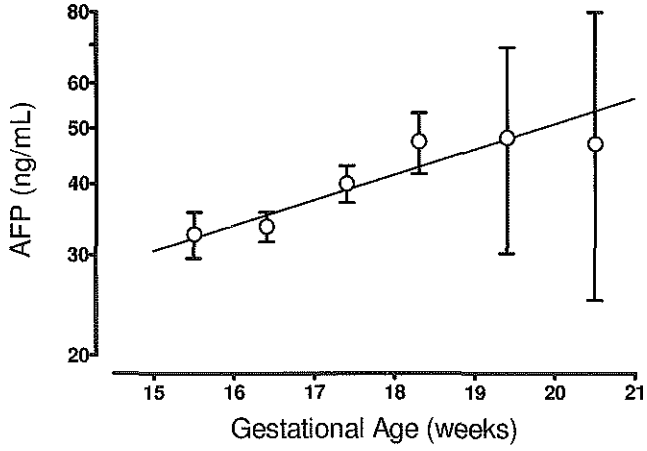

Figure 54-6 Computation of median values for maternal serum alpha fetoprotein (AFP) in the second trimester. The observed average gestational age from Table 54-4 is plotted on the horizontal axis and the median of that week's AFP measurements on the vertical logarithmic axis. The thin vertical lines represent the 95% confidence intervals of the medians. The line represents the results of a linear regression analysis of log AFP versus age weighted by the square root of the number of samples. The equation of that line in completed weeks is median $AFP = 10^{0.04465 \times (weeks) + 0.8334}$. The corresponding equation for day-specific medians is median $AFP = 10^{0.006378 \times (days) + 0.8142}$.

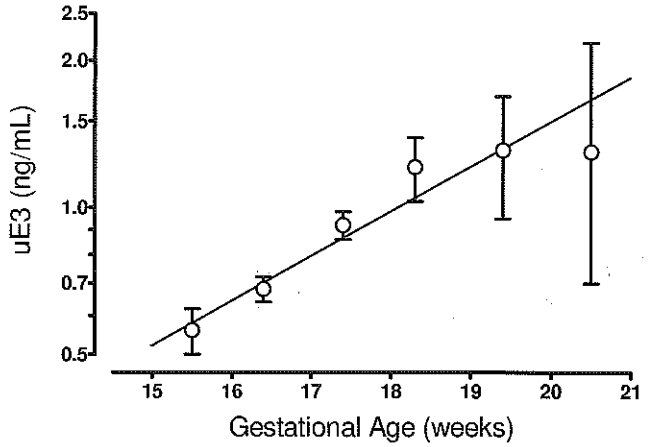

Figure 54-7 Computation of median values for maternal serum unconjugated estriol (uE_3) in the second trimester. The observed average gestational age from Table 54-4 is plotted on the horizontal axis and the median of that week's uE_3 measurements on the vertical logarithmic axis. The thin vertical lines represent the 95% confidence intervals of the medians. The line represents the results of a linear regression analysis of log uE_3 versus age weighted by the square root of the number of samples. The equation of that line in completed weeks is median $uE_3 = 10^{0.09165\times(\text{weeks})-1.618}$. The corresponding equation for day-specific medians is median $uE_3 = 10^{0.01309\times(\text{days})-1.657}$.

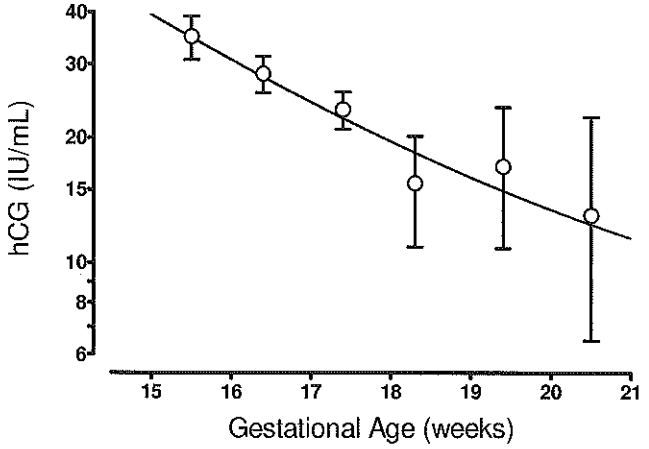

Figure 54-8 Computation of median values for maternal serum chorionic gonadotropin (CG) in the second trimester. The observed average gestational age from Table 54-4 is plotted on the horizontal axis and the median of that week's CG measurements on the vertical logarithmic axis. The thin vertical lines represent the 95% confidence intervals of the medians. The line represents the results of a nonlinear regression analysis weighted by the square root of the number of samples. The equation of that curve in completed weeks is CG median = $39.69 \times e^{-0.3001\times(\text{weeks}-14)} + 5.93$. The corresponding equation for day-specific medians is CG median = $45.14 \times e^{-0.04287\times(\text{days})} + 5.93$.

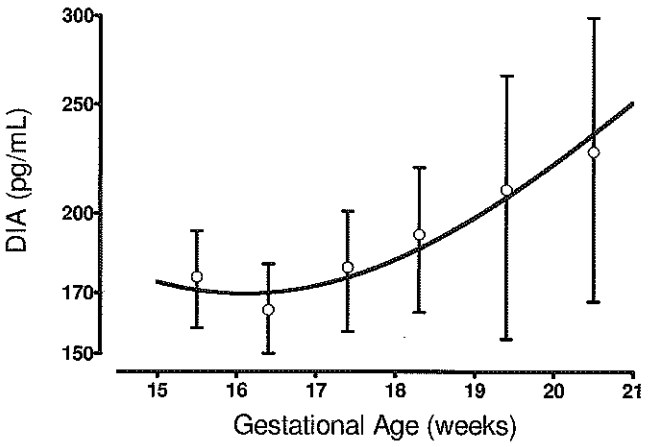

Figure 54-9 Computation of median values for maternal serum dimeric inhibin A (DIA) in the second trimester. The observed average gestational age from Table 54-4 is plotted on the horizontal axis and the median of that week's DIA measurements on the vertical logarithmic axis. The thin vertical lines represent the 95% confidence intervals of the medians. The line represents the results of a quadratic regression analysis weighted by the square root of the number of samples. The equation of that curve in completed weeks is DIA median = $3.404 \times \text{weeks}^2 - 106.7 \times \text{weeks} + 1005.7$. The corresponding equation for day-specific medians is DIA median = $0.06947 \times \text{days}^2 - 15.66 \times \text{days} + 1052$.

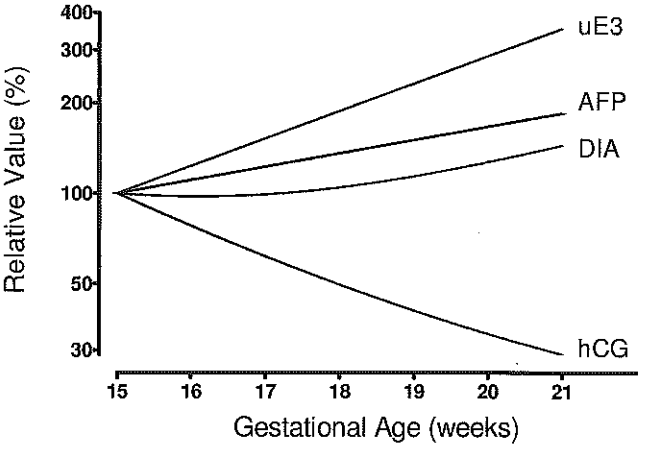

Figure 54-10 A comparison of the associations between gestational age and the four second trimester maternal serum markers for Down syndrome. For each of the analytes, the median at 15 weeks gestation has been assigned a value of 100%. Each subsequent median is represented as a percentage of that initial median. The marker that has the weakest association with gestational age is dimeric inhibin A (DIA). The strongest associations are found for unconjugated estriol (uE_3) and chorionic gonadotropin (CG). The association between gestational age and alpha fetoprotein (AFP) is intermediate.

TABLE 54-5 Observed and Regressed Day-Specific Medians for Unconjugated Estriol During the 17th Week of Gestation

Gestational Age (Week, day)	Number of Observations	uE_3 (ng/mL) Observed	Regressed
16,0	195	0.67	0.68
16,1	225	0.69	0.70
16,2	228	0.71	0.72
16,3	219	0.76	0.74

16,5	191	0.80	0.79
16,6	175	0.78	0.81

strongest association with gestational age is found for uE_3 and CG measurements. This association indicates that errors in dating will have the greatest impact on these two tests.

Some laboratories use "day-specific" medians rather than weekly medians (i.e., a different median value is used for each day of pregnancy). Although individual pregnancies cannot be reliably dated to within 1 day, there is a consistent day-by-day change in analyte concentrations if a group of pregnant women is observed. Table 54-5 shows the observed and regressed medians for uE_3 for a group of ultrasound-dated women in their 17th week of gestation. The observed median levels clearly increase during that week. The regressed median for 16 weeks, 0 days, is quite different from the median for 16 weeks, 6 days. If weekly medians were to have been used instead, all of these samples would have been interpreted against a single median—about 0.74 ng/mL (0.74 μg/L).

The second method is an acceptable alternative. The laboratory must identify an established laboratory that is willing to share its reliable median values. Then, 25 to 50 specimens are assayed at each laboratory. These specimens are selected so that their results span the analytical measurement range. The two sets of values can then be compared using linear regression analysis (after appropriate transformations) to establish the relationship between the two assays. The regression equation can then be applied to the reliable set of median values to derive a set of medians appropriate for the laboratory. These median values can be used temporarily until values from 300 to 500 patients are available for the analysis provided earlier.

Laboratories must update existing median values in several situations. Significant differences in values on the same patient specimens are common when using either a new lot of the reagents or reagents from a different manufacturer. In this situation, the relationship between the new and old methods can be established by regression analysis of values measured on the same patient specimens as described in the second method in the previous paragraph. If a periodic adjustment is required, the laboratory should carefully choose the characteristics of the population to be used (e.g., race, method of dating, and time period) and verify that the assay has been providing consistent results over the time period of interest. This can be done by routinely monitoring the median MoM over time (epidemiological monitoring) as discussed in more detail later in this chapter. The resulting data are then analyzed as indicated in the first method described previously.

Adjustments for Factors That Influence Analyte Measurements

Prenatal screening for both open neural tube defects and Down syndrome is optimized when each woman's analyte concentration is compared with other women (the reference group) who are "similar" to her in many respects.[151] In addition to gestational age, this "similarity" extends to other factors that have been shown to affect the analyte concentrations, including maternal weight, race, insulin-dependent diabetes (IDD), and multiple pregnancy. Taking into account these factors increases the accuracy of the interpretation. These factors are taken into account by dividing the patient's MoM value by a factor corresponding to the ratio of the MoM values found in those without the factor to the MoM values in those with the factor. A meta-analysis of the data supporting the following recommendations has been published.[151]

Maternal Weight

As maternal weight increases, the average concentration of analyte values decreases, perhaps because a fixed amount of analyte is diluted in an increased maternal blood volume. For example, heavier women have, on average, lower AFP values and are less likely than lighter weight women to be screen-positive for neural tube defects. Without taking maternal weight into account, screening is less effective in heavier women because their MoM values are inappropriately low. The importance of adjusting AFP MoM values for weight is reinforced by recent studies showing that heavier women have a twofold to threefold increased risk for open spina bifida.[339] The weight effect is also significant for CG and DIA, but less so for uE_3 (Figure 54-11). Maternal weight is taken

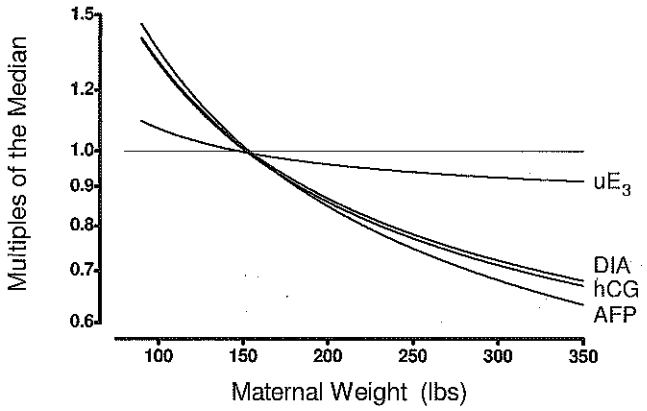

Figure 54-11 The relationship of AFP, uE_3, CG, and DIA (expressed as multiples of the median [MoM]) and maternal weight. The horizontal line at 1.0 MoM is the value found for a woman of average weight.

into account by adjusting each woman's MoM values by a factor corresponding to the expected MoM value in Figure 54-11 for average women with her weight. These factors are empirically derived from the screened population in a manner that is similar to deriving median analyte concentrations for each gestational age. Optimally, each laboratory should derive its own maternal weight adjustment factors for each analyte, because the average maternal weight may differ from that seen in other laboratories. These adjustment factors should be applied only over the maternal weight range in which they have been shown to be appropriate. For example, if few or no data are available to derive adjustment factors for women weighing more than 350 pounds, then the laboratory should be careful in extrapolating factors to these women from data on women of lower weight. Laboratories should limit the range of adjustment using upper (and lower) truncation limits. If a woman's weight is outside these limits, adjustment should be applied as if the woman were at the respective limit. An effective model for all analytes is a linear reciprocal model. Maternal weights are stratified into weight groups and regressed against the reciprocal of maternal weight. This model and its application have been described in detail elsewhere.[151,233] Although not routine, some screening programs have implemented separate weight adjustments for selected racial groups because of systematic differences in maternal weight. Although this would theoretically improve performance, there is little evidence that the increased complexity and propensity for error are warranted. Obesity is associated with a threefold to fourfold increase in risk for open neural tube defects.[290,339] There is no reported association between maternal weight and Down syndrome.

Maternal Race

African-American women have maternal serum AFP and CG concentrations that are 10% to 15% higher than those found in Caucasian women.[151] Adjustment for this difference can be accomplished in two ways. The first approach is to calculate an MoM value for African-American women using medians derived from the Caucasian population, and then to divide the resulting MoM by a factor corresponding to the ratio between values in the two populations (i.e., 1.10 to 1.15). For example, if an African-American woman has a maternal serum AFP MoM of 1.60 calculated using median values from the Caucasian population, her adjusted MoM is 1.45 (1.60 ÷ 1.10). The second approach is to calculate a separate set of medians using values measured on the African-American population. uE_3 and DIA do not appear to differ in these two populations. Only limited data are available for other racial/ethnic groups and therefore routine adjustments are not generally performed. Although there is little evidence that the age-specific birth prevalence of Down syndrome differs by race, there is strong evidence that the birth prevalence of open neural tube defects in African-American women is half or less that of Caucasian women from the same geographic region.[142A] Thus at any given maternal serum AFP MoM, an African-American woman has half the risk of a Caucasian woman of having a pregnancy affected by an open neural tube defect. Some programs have addressed this "disparity" by moving the cutoff higher for African-American women. For example, the risk for the Caucasian woman at 2.0 MoM is similar to that for the African-American woman at 2.5 MoM. However, programs that do this must acknowledge that the detection rate (and false-positive rate) will be lower in the population with the higher screening cutoff. Limited information is available on the AFP concentrations in African-American women with an open neural tube defect, but what is published indicates that screening in this population should be equally effective.

Insulin-Dependent Diabetes

Maternal serum AFP values in women who have IDD before pregnancy have been reported to be systematically lower by about 20%.[151] This difference is taken into account by dividing the computed MoM value in women with IDD by 0.8, the ratio of maternal serum AFP values found in the two populations. After adjustment, the proportion of women with IDD at or above any given MoM cutoff should be approximately equal to that found in the general population. It is not possible to define the associated detection rate for open neural tube defects because no large series of maternal serum AFP measurements in IDD women with a fetus affected with an open neural tube defect have been published. In a recent study, the expected lowering of maternal serum AFP concentrations in pregnant women with IDD was not observed.[284] Because these women are now carefully monitored to help ensure appropriate blood glucose concentrations, it is speculated that this tight control might account for the finding of no effect.

It has been recommended that in locations where women with IDD are carefully monitored to maintain glucose control, adjustment of maternal serum AFP is no longer warranted.[284] This recommendation poses a dilemma for screen-

ing laboratories. In the absence of this detailed patient information, the screening program must determine whether or not routine adjustment of maternal serum AFP levels for IDD status is warranted.

There is no compelling evidence that the rate of Down syndrome births in women with IDD is substantially different from that in the general population.[172] However, there is evidence that birth prevalence of open neural tube defects is higher by up to a factor of 5.[1] Thus at a given AFP MoM concentration, women with IDD are at a substantially higher risk of open neural tube defects than the general population. This can be taken into account by lowering the AFP MoM cutoff from, for example, 2.0 to 1.5.

Current information suggests that maternal serum AFP concentrations are not altered among women with gestational diabetes, even if insulin is subsequently required later in pregnancy.

In women with IDD, uE_3 and CG MoMs are on average 8% and 7% lower, respectively, than in nondiabetic women.[151] These differences are small, and whether or not they are taken into account will have little impact on the resulting Down syndrome risk. The impact of IDD on DIA results is more variable, ranging from 0.91 MoM to 1.17 MoM (weighted average of 1.06 MoM), and adjustment is not yet warranted.[337A]

Twin Pregnancy and Open Neural Tube Defect

Maternal serum AFP concentrations in twin pregnancies are about twice the concentration found in singleton pregnancies (i.e., 2.0 MoM).[151] Among singleton pregnancies with open spina bifida, the median serum AFP MoM is about 3.5.[330] Thus the expected maternal serum AFP in the average twin pregnancy affected with open spina bifida might be around 4.5 MoM (1.0 MoM contributed by the unaffected fetus and 3.5 MoM from the fetus with open spina bifida). Screening performance in twin pregnancies will therefore not be as effective as in singleton pregnancies since the AFP distributions are less separated. Although most affected twin pregnancies are discordant for open neural tube defects, if both twins are affected (seen in about 5% of affected twin pregnancies), screening performance can be expected to approach that in singleton pregnancies.

Twin Pregnancy and Down Syndrome Screening

Calculation of Down syndrome risk requires that the distribution of analyte values for all tests in both unaffected and affected pregnancies be known. These distributions are well defined for AFP, uE_3, CG, and DIA in singleton pregnancies, and thus reliable risks can be calculated. The distributions of these analytes also are available for twin pregnancy unaffected by Down syndrome; the average MoMs in unaffected twin pregnancy for AFP, uE_3, CG, and DIA are about 2.0, 1.7, 1.9, and 2.0, respectively.[151] Fewer data are available for concentrations of these analytes in twin pregnancies affected with Down syndrome. A further complication is that in approximately one third of pregnancies, both twins will be affected (monozygotic), and in two thirds of pregnancies, only one twin will be affected (dizygotic). Screening will be less effective when only one twin is affected. Another difficulty is that the prevalence of Down syndrome is not well defined in twin pregnancies. Based on the rate of monozygotic and dizygotic twins, the prevalence of Down syndrome would be predicted to be 1.67 times higher in twin pregnancies. Published data indicate that the prevalence in twin pregnancies is actually similar to that found in singleton pregnancies.[110]

Given these limitations, calculation of only an approximate risk (sometimes called a pseudorisk) for twin pregnancy is possible.[234] This is accomplished by dividing the MoM value for each analyte by the corresponding average found in the unaffected twin pregnancy. The twin pregnancy risk is computed in the same way as for singleton pregnancies. The same risk cutoff used to identify women with singleton pregnancies is used to identify women with twin pregnancies as being screen positive.

This twin screening protocol will: (1) correctly rank the pregnancies from highest to lowest risk, and (2) yield a screen-positive rate similar to the rate found for singleton pregnancies at any given screening cutoff. The Down syndrome pseudorisk, however, may not be correct, and it is recommended that this risk not be routinely reported. Screen-positive women with twin pregnancies can be informed that their test results place them in a high-risk group, but that their actual risk is uncertain. Interpretation of risk for triplets and higher gestations is not recommended because of the limited data available. Additional factors that need to be considered when offering such screening are the increased difficulty and fetal loss associated with multiple needle insertions necessary during amniocentesis, and the loss of the unaffected twin should an affected twin be identified and selectively terminated.[117]

Other Tests and Combinations of Tests

Several other maternal serum analytes have been reported to be associated with Down syndrome in second trimester maternal serum, including the free alpha and free beta subunits of CG[44,210,333] and β1-glycoprotein[29] and DIA.[154,344] Of these, only DIA has been shown to provide any significant advantage in combination with the triple test. Two analytes found in maternal urine have been investigated as tests for Down syndrome screening. Early studies reported that urinary gonadotropin peptide, a metabolite of CG, had the best screening performance of any proposed test (80% for a 5% false-positive rate).[60,87] These early studies have not been confirmed.[88,170] Attention has now turned to another urinary analyte, invasive trophoblast antigen or ITA (also called hyperglycosylated CG). One study reported a detection rate of 79% for a 5% false-positive rate,[73] while another reported less favorable results.[89] A recent retrospective study concluded that serum ITA could effectively replace CG or free CGβ in a multianalyte panel.[252] A large prospective study is

currently underway to determine the screening performance in routine practice.

Down Syndrome Screening in the First Trimester of Pregnancy

Most screening programs recommend testing mothers between 16 and 18 weeks gestation, but will accept specimens collected from 15 to 20 weeks or later. Screening pregnancies after 20 weeks gestation allows little time for further testing and increases the difficulty of decision-making for the couple. Attention is now being focused on moving Down syndrome screening to the first trimester of pregnancy (at 10 to 13 weeks of gestation). Both ultrasound findings and serum tests have been identified for first trimester application. First trimester values of maternal serum pregnancy associated plasma protein-A (PAPP-A) are low and free CGβ values elevated in cases of Down syndrome.[126] In combination with maternal age, these two serum tests yield a detection rate of 60% at a 5% false-positive rate.[155] This screening performance is inferior to quadruple test screening in the second trimester.[154] Ultrasound measurements of nuchal translucency (NT), the subcutaneous space between the skin and cervical spine, have been shown to be increased in fetuses with Down syndrome.[237,307] Increased NT measurements are also a nonspecific finding for many fetal structural abnormalities, and therefore are only useful as a screening test.[248] NT measurements alone can detect 60% or more of the Down syndrome cases at a 5% screen positive rate, making NT the best single screening test described to date.[335]

Neither ultrasound findings nor serum tests in the first trimester have sufficient predictive power to be used alone. In 1997, it was estimated that a combination of NT and serum tests (the combined test) could detect 85% of Down syndrome at a 5% false-positive rate. If confirmed, this would be the best Down syndrome screening test available.[335] The combined test is widely available in Europe and is being increasingly offered in the United States. Although first trimester screening would have obvious advantages, it also has limitations. To be reliable, NT measurements must be performed at specialized referral centers that employ sonographers who have undergone rigorous training and participate in on-going quality control programs. Routine office ultrasound is unsuitable for obtaining this measurement. Therefore access for women in rural areas will be limited. If first trimester diagnostic testing is to be performed, it will have to include chorionic villus sampling (CVS). CVS is less safe than amniocentesis performed in the second trimester of pregnancy,[58] and may not be readily available. Several studies have shown that Down syndrome fetuses with increased NT and low PAPP-A are spontaneously aborted at a higher rate than for those with normal NT measurements.[248] Thus the real screening performance may be lower than expected,[86,90] and many Down syndrome fetuses identified in the first trimester will spontaneously abort in the absence of screening. If screening for Down syndrome were to be moved to the first trimester, routine screening for open neural tube defects using maternal serum AFP would still need to be performed, as such screening is not effective in the first trimester.[330,334] Lastly, NT measurements are likely to be expensive in the United States, as first trimester ultrasound examinations are not routine, and third party payers may be reluctant to pay. Despite these shortcomings, first trimester screening is a recommended option on the condition that appropriate diagnostic testing is available locally.[6]

Combining First and Second Trimester Screening into a Single Integrated Test

An innovative approach to combining the best of the first and second trimester tests has been proposed that avoids most of the limitations of stand-alone first trimester screening—the integrated test.[338] With this approach, measurements of NT and PAPP-A are made in the first trimester but not interpreted or acted upon until the second trimester. In the second trimester, a second serum is drawn and a quadruple test performed. Results from all six tests (NT, PAPP-A, AFP, uE_3, CG, and DIA) are combined into a single risk estimate for interpretation in the second trimester. It is projected that this approach could detect 85% of Down syndrome cases with only a 1% false-positive rate. A recent study (SURUSS) involving results from 47,507 pregnancies at multiple centers obtained results consistent with this estimate.[337]

Reporting Individual Results

The maternal serum screening report should contain the following information: the concentrations and MoM values of the measured analytes, the Down syndrome risk estimate (along with risks for other abnormalities such as trisomy 18), an interpretation as either screen-positive or screen-negative, and an interpretation of the information that includes possible further actions. The physician-provided information should include specimen collection date, identification as a first or second specimen, date of LMP or gestational age by ultrasound, maternal birth date (or age), relevant family history, number of fetuses (if known), maternal race, and the presence or absence of maternal diabetes requiring insulin therapy.

Calculating Individualized Patient-Specific Risks With Use of Biochemical Measurements

Calculating an individualized risk (patient-specific risk) for any given condition is accomplished by multiplying the *a priori* risk for that condition by a likelihood ratio that is calculated using the woman's analyte measurements (i.e., patient risk = *a priori* risk × likelihood ratio). This basic equation is used to calculate patient-specific risk for neural tube defects, Down syndrome, trisomy 18, or any other condition in which the distributions of tests for the unaffected and affected population have been defined. The *a priori* risk is obtained from large epidemiological studies that ascertain the prevalence for the condition under consideration. For

example, a woman's age is used to define her *a priori* risk for having a fetus with Down syndrome. The likelihood ratio is determined by calculating the ratio of the heights of the affected and unaffected overlapping population distributions for any specified MoM value. When multiple tests are used, a single likelihood ratio is calculated using the overlapping distributions for each test but with the correlation between the tests taken into account. Complete details for calculating risks are available on this book's accompanying Evolve Web site, found at http://evolve.elsevier.com/Tietz/textbook/.*

Use of Epidemiological Monitoring in Quality Control

In prenatal screening the interpretative unit for each analyte is the MoM, which takes into account variables such as gestational age, maternal weight, race, and IDD. Expressing these results in MoMs allows the calculation of a patient-specific risk for Down syndrome. One of the most common causes of poor laboratory performance is the use of incorrect median values, either because those values are inappropriate for the kit being used or because systematic shifts in the assay values have occurred. Poor performance can also occur when a kit is nonspecific or relatively inaccurate. Ensuring that median values (and by extension the MoM values) are accurate is one of the most important responsibilities of the screening laboratory. The following discussions are adapted from Knight and Palomaki,[184] a publication that discusses in detail the process of epidemiological monitoring.

Definition of Epidemiologic Monitoring

A powerful method for evaluating and monitoring the appropriateness of medians is epidemiologic monitoring. This process involves gathering data from the screened population to allow calculation of the detection rate (proportion of affected pregnancies with positive test results) and the false-positive rates (proportion of unaffected pregnancies with a positive test result). These rates can then be compared with expectations. Obtaining a detection rate is difficult because complete ascertainment of all pregnancy outcomes is required, and it can take years before a sufficient number of affected pregnancies occurs to achieve reliable estimates. In practice, the false-positive rate is used for epidemiologic monitoring because a reliable estimate can be calculated in a short time and it is not necessary to have outcome information. For prenatal screening, the false-positive rate is defined as the proportion of women with test results falling at or above a specified AFP MoM (for open neural tube defect screening), or with a Down syndrome risk at or above the specified risk cutoff (Down syndrome screening). However, these rates are not actually false-positive rates, because a few of the screen-positive individuals are actually true-, rather than false-, positive results (i.e., they do have an affected fetus). For this reason, the term initial positive rate (IPR) has been suggested, because it more accurately describes what is being calculated. The IPR can be used to assess whether medians are appropriate, since it will be shifted upward or downward if medians are incorrect for the population being screened. Further, once the IPR is shown to be within acceptable limits, continuous monitoring can help detect shifts in assay values.

Epidemiologic Monitoring of Open Neural Tube Defect Screening

In maternal serum AFP screening for open neural tube defects, the IPR is the proportion of women with values above the specified MoM cutoff. For most screening programs, the two most commonly used screening cutoffs are 2.0 and 2.5 MoM; these cutoffs produce IPRs of 3% to 5% and 1% to 3%, respectively. When new medians are implemented, the IPR can be used to determine if the medians are appropriate by comparing the expected with the actual IPRs. If the IPR falls outside the expected range, it is possible that the medians are incorrect for the assay being used or for the population being screened (assuming that the AFP assay is known to be reliable). For example, if the IPR at a cutoff of 2.5 MoM is 5%, median values may be too low. Thus more women will have results above the 2.5 MoM cutoff.

Once the IPR is shown to be within an acceptable range, ongoing monitoring of this rate serves as a check on shifts in assay calibration caused by changes in kit lots, reagent deterioration, poor technical performance, and other factors. Simultaneous monitoring of the IPR and the results of quality control samples can facilitate identification of shifts in assay values. If, for instance, the IPR at a 2.5 AFP MoM cutoff increases from 2% to 4%, and at the same time some or all of the values of quality control (QC) samples shift significantly upward by 10% or more, the change is consistent with an upward shift in assay calibration. The IPR increases when the assay values increase because individual AFP values are interpreted by using medians generated from data gathered in the past. In the example given above, it may be necessary to calculate new medians or adjust existing median values to take into account the assay shift.

It is difficult to provide an absolute rule as to how large a change in the IPR is sufficient to warrant recomputing medians as factors other than the assay can affect the IPR. For example, a significant increase in the number of pregnancies dated by ultrasound will reduce the IPR, because incorrectly dated pregnancies will be identified before the AFP test is done. However, consider that an upward shift in AFP values of just 10% can increase the IPR by more than 50% (e.g., from 2% to 3%) with little gain in detection. In effect, more interventions (ultrasound examinations or amniocenteses or both) will be required to detect each case of neural tube defect. Therefore if a change in the IPR of 50% or more occurs simultaneously with an identifiable shift in assay values of 10% or more, medians need to be recalcu-

*References 86A, 91A, 116A, 150A, 160A, 184A, 225A, 239A, 271A, 332A, 332B, 333A, 335A.

lated. Laboratories may wish to have stricter warning limits (e.g., shifts of 25% or more in the IPR occurring simultaneously with a change of 7% or more in quality control samples). In applying these rules, enough values should be used to ensure that a reliable IPR can be calculated (generally 300 to 500 values will ensure reliability) and that observed changes are statistically significant. Further the change should be persistent and occur over several kit lots. Otherwise the laboratory may be tracking random error. IPR values can also be calculated using a moving window to improve reliability. For example, consider a laboratory that screens 300 women per month. In addition to calculating a monthly IPR, the lab could calculate a cumulative 3-month moving window (i.e., each month, the current month's data are added and the oldest month is dropped). The actual time period for both the individual and a cumulative moving window will be determined by how many samples are screened per unit time by any given laboratory.

Epidemiological Monitoring of Down Syndrome Screening

In screening for Down syndrome, the IPR is the proportion of women with a risk at or above the risk cutoff. In contrast to neural tube defect screening, the IPR for Down syndrome screening is influenced by each of the analytes used in the risk calculation. Therefore monitoring the IPR does not provide information on which assay(s) might be responsible when an inappropriate IPR is obtained. Consequently, it is necessary to individually monitor each assay separately. Individual monitoring of each assay can be accomplished according to the following rationale. When individual MoM values are calculated for each patient using gestational age–specific medians, MoM values can be analyzed collectively without regard for the gestational week. If the medians are appropriate, the resulting distribution of MoM values will have a grand median MoM of 1.00. The center of the distribution is typically expressed as the median, rather than as the mean, because MoM distributions are not Gaussian on the linear scale.

The initial application of the grand MoM is to ensure that when medians are first implemented they are appropriate for the assay and population being screened. This is accomplished by calculating the grand MoM using values from 300 to 500 individuals screened after the new set of medians is implemented. The grand MoM should be 1.00, within statistical limits. A convenient approach is to plot the grand MoM values on a graph, facilitating the detection of trends. The IPR observations can also be plotted on the same graph. If the IPR begins to trend in either a positive or negative direction, the grand MoM for each assay can be examined to determine if one of the analytes is paralleling the IPR change. If a significant change in one of the assays has occurred, corrective action should be taken (e.g., recalculating medians). For example, suppose the IPR shows a significant upward trend (e.g., from 6% to 9%), and over the same time period the median MoM of the uE_3 assay significantly decreases (e.g., from 1.03 to 0.91). Since decreasing uE_3 values are associated with increasing risk for fetal Down syndrome, it is possible that the change in the uE_3 assay is responsible for the increase in the IPR. The next step would be to examine quality control specimen values to determine if a corresponding downward shift in values has occurred. If a shift has occurred, it may be necessary to recalculate and implement a new set of uE_3 medians using data collected after the time when the change in the uE_3 assay occurred (or apply an adjustment factor to the old medians). A simultaneous change in two assays can complicate monitoring, because the IPR might not change if the shift in one analyte value increases risk and the other analyte decreases risk. Simultaneous monitoring is therefore recommended of the IPR and the median MoM for each analyte. When interpreting median MoM values, rates should be calculated only when enough patient values are available (typically, 300 to 500 samples) to ensure a statistically reliable rate. Further, a single IPR or median MoM that deviates from the expected one should serve as only a warning to examine quality control data more closely.

Laboratories need to have an action limit in place to determine how much variability is to be allowed in the grand MoM. To do this, consider the impact on the Down syndrome detection rate and the IPR of a 10% downward shift in the uE_3 values (grand MoM of 0.90). This can be simulated by recalculating MoM values after assay values are artificially shifted down by 10%, followed by mathematical modeling of the detection rate and associated IPR. Such an assay shift effectively changes the MoM for any given sample, because current assay values are interpreted using reference data collected in the past. When uE_3 values shift downward by 10%, the detection rate increases only slightly from 59% to 62%. However, the IPR increases from 4.8% to 6.7%, a 40% increase. Thus what might be viewed as a small shift in assay values has a large impact on the IPR, with little corresponding gain in detection. Similar but somewhat smaller effects are seen when considering similar shifts in AFP and CG measurements. The relatively large changes in the IPR with relatively small shifts in assay values are some of the primary reasons for closely monitoring assays to ensure that the amniocentesis referral rate is maintained within reasonable limits. Given these facts, screening laboratories should consider, as a minimum, a consistent deviation of 10% from 1.00 MoM (range 0.90 to 1.10) as important. Laboratories may wish to consider setting up more strict warning limits, such as 7% (assuming this percentage is based on sufficient numbers of samples to yield statistically significant results). With this limit, median MoM values outside the range of 0.93 to 1.07 MoM would be considered sufficiently deviate to warrant further investigation to determine if a problem exists.

Although the IPR for laboratories screening for Down syndrome using multiple tests is generally between 5% and 10% in an unselected pregnancy population, it may be affected by various factors (other than incorrect medians),

including the number of tests used, the screening cutoff chosen, and the maternal age distribution of the screened population. For example, if screening is being applied primarily to older women, the IPR will be substantially higher because older women are collectively more likely to be screen-positive because of their higher age-specific risks. For example, if the triple test is being used to screen women of age 35 and older at a term risk cutoff of 1 : 250, approximately 25% of women will be screen-positive.[153] The method of gestational dating will also affect the IPR. Laboratories with a high percentage of pregnancies dated by the first day of the LMP will have a higher IPR than do laboratories where most gestational ages have been provided from ultrasound measurements.[149]

External Proficiency Testing

All laboratories performing prenatal screening must participate in an external proficiency testing program that distributes unknown specimens that reflect the concentrations of analytes found near the middle of the second trimester of pregnancy. These programs also evaluate the laboratory's ability to convert analyte values into an MoM using the laboratory's own median values, to make screening recommendations, to adjust for variables that influence analyte values, and to calculate patient-specific risks. Two such external proficiency testing programs for prenatal screening are currently available in the United States. The Foundation for Blood Research and the CAP sponsor a joint program (FBR/CAP Maternal Screening Survey FP) serving approximately 300 laboratories. Five serum and two amniotic fluid proficiency samples are distributed three times each year. The FBR/CAP program also has a special topic in each distribution that allows FP Survey participants to obtain CME/CEU credits. New York State also has an external proficiency testing program that is required for laboratories serving New York State residents. Five serum and five amniotic fluid samples are distributed three times each year. Neither survey includes first trimester serum tests (free beta CG and PAPP-A). The Foundation for Blood Research also sponsors an amniotic fluid AFP/AChE proficiency testing program for diagnostic laboratories. Five amniotic fluid samples are distributed three times each year.

LABORATORY TESTS

In this section of the chapter, we review methods for measurements of CG, AFP, uE_3, DIA, fetal fibronectin, and amniotic fluid bilirubin, and six tests for fetal lung maturity.

Chorionic Gonadotropin

Measurement of CG can be used to detect pregnancy and its abnormalities (e.g., ectopic and molar pregnancies), to screen for Down syndrome and trisomy 18, and to monitor the course of a patient with a CG-producing cancer. Because CG has these diverse uses, many assays are used, including qualitative urine and serum kits and quantitative serum assays. Cole has published reviews of CG methods.[72,77]

This hormone is commonly called "human chorionic gonadotropin" and often abbreviated hCG or HCG. This term and its abbreviations should be abandoned because the adjective "human" is superfluous.[229] Nonetheless, when communicating with clinicians (at least in the United States), hCG is the preferable term to avoid misunderstanding.

Chemistry

CG is a glycoprotein containing a protein core with branched carbohydrate side chains that usually terminate with sialic acid. The hormone is a heterodimer composed of two nonidentical, noncovalently bound glycoprotein subunits, alpha (α) and beta (β). When the CG dimer is dissociated, the hormone activity is lost. However, a major part of the original activity is restored by equimolar recombination of the two subunits.

The CG carbohydrate composition changes as pregnancy progresses. At the time of implantation in normal pregnancies, more than 80% of immunoreactive CG is a large molecular mass form (Mr 41,000 to 42,000) called hyperglycosylated CG (H-CG).[240] Later in pregnancy, a 36,000 to 37,000 molecular mass form predominates. The CGα subunit contains 92 amino acids, two carbohydrate side chains, and five disulfide bridges. The molecular weight of the α-subunit is estimated to be 14,900 of which 10,200 is the protein component. CGβ consists of 145 amino acids and has six carbohydrate side chains and six disulfide bridges. The molecular mass of CGβ is estimated to be 23,000. Thus the heterodimer has a molecular weight of approximately 37,900 and has a higher carbohydrate proportion than any other human hormone.

In maternal serum, CG can be in many forms, including unmodified CG dimer with differing oligosaccharides and forms modified by varying degrees of degradation. In a normal pregnancy, differences in oligosaccharides produce seven charge isomers with isoelectric points from pH 3.8 to pH 4.7.[75] Serum enzymes cleave peptide bonds in CGβ at position 44-45 (and, after prolonged incubation, at 51-52) to form nicked CG (CGn).[180] The nicking inactivates the hormone and also reduces ability to bind some CG antibodies. Other nicking sites are at β44-45, β47-48, and α70-71.[42,229] Both free CGα (fCGα) and free CGβ (fCGβ) are found in the serum, along with nicked free forms (e.g., fCGβn). In the second trimester, more than 99% of CG is the dimer form; only a small amount circulates as free β-subunit.[152] The C-terminal portion of fCGβ can be cleaved to create a core fragment of CGβ (CGβcf), which is composed of two pieces of the β-subunit, residues 6-40 and residues 55-92, held together by disulfide bridges.[41] CGβcf has a molecular mass of 13,000.

Urine contains predominantly CGβcf and to a lesser degree unmodified CG and CGn. Clearance occurs both in the liver and through the kidneys and varies for the differ-

ent CG forms. Hepatic clearance[342] is approximately 2 mL/min/m^2, and renal clearance is approximately 0.4 mL/min/m^2; thus early morning urine specimens have CG concentrations comparable with those in serum. A study using highly specific immunoassays for CG, CGβ, and CGα found that the disappearance after term pregnancy was triphasic.[188] The rapid, medium, and slow half-lives were, respectively: CG, 3.6, 18, and 53 hours; CGβ, 1.0, 23, and 194 hours; and CGα, 0.63, 6, and 22 hours.

Biochemistry

CG is synthesized in the syncytiotrophoblast cells of the placenta. Minute amounts are also made in the pituitary of men and nonpregnant women, and, like many other pituitary hormones, it is secreted in a pulsatile fashion.[242] A single gene located on chromosome 6 encodes the α-subunit of all four glycoprotein hormones (TSH, LH, FSH, and CG). Chromosome 19 contains a family of seven genes that encode the CGβ subunit, though only three appear to be active.[265] Separate messenger RNAs are transcribed from the respective genes, and the α- and β-subunits are translated from each. The subunits spontaneously combine in the rough endoplasmic reticulum and are then continuously secreted into the maternal circulation.

Synthesis of CGβ peaks at about 8 to 10 weeks, but production of the α-subunit continues to increase and appears to be a function of the mass of the placenta. The production of CGβ in the syncytiotrophoblasts may be under paracrine control of gonadotropin-releasing hormone (GnRH) produced in cytotrophoblasts. Studies suggest that the cytotrophoblasts produce inhibin, which stimulates CG production.[257] The number of cytotrophoblasts peaks at about the same time the CGβ production peaks.

Extensive homology exists between the peptide portions of CGβ and LHβ subunits. Investigators have proposed that a single deletion in the ancestral LHβ gene lengthened the subunit from 115 amino acids to 145 amino acids; 80% of the first 115 amino acids in both β-subunits are identical, but 20 additional amino acid residues are unique in CGβ.[310]

Physiology

CG stimulates the corpus luteum in the ovary to make progesterone during the first weeks of pregnancy. The placenta makes inadequate amounts of progesterone during this time. No specific receptor for CG is known; it binds to and activates the LH receptor in cells of the corpus luteum in the maternal ovary. Species other than primates and horses use LH for this function. The glycation of the α-subunit has a dominant role[283] in signal transduction, an increase in intracellular cyclic adenosine monophosphate (cAMP). The cAMP increase in turn stimulates the production of progesterone, a steroid that prevents menses and thus facilitates the pregnancy. CG binds weakly to TSH receptors in the maternal thyroid; thus CG concentrations greater than 1 million IU/L are thyrotropic.

CG Assays

Many assay techniques have been used for determining CG. All modern techniques use immunoassay. Vaitukaitis and colleagues took advantage of the uniqueness of CGβ to produce the first specific assay for CG, which used polyclonal antibodies raised against the β-subunit.[323] Since then, highly specific monoclonal antibodies have been produced that recognize only epitopes on the last 30 amino acid residues of the CGβ. Many of these have low affinity. Highly specific monoclonal antibodies having high affinity have been produced that bind to unique epitopes in the first 115 amino acids.[59] These antibodies are the most frequently used in assays that measure CG.

Bioassays, receptor assays, and agglutination inhibition assays are obsolete for detecting pregnancy. The historical bioassays are interesting because they exploit the physiological effect of CG. A further discussion of bioassay[66,68,114,286] and agglutination inhibition assays[313] is available on the Evolve site that accompanies this book.

Qualitative CG Tests

In the United States, about 30 urine or serum point-of-care CG tests and 25 home tests are available. The FDA web site[321] lists the products under device codes LCX, DHA, JHI, JHJ, and LFS.

Home test kit assays are the most commonly used pregnancy tests in the United States. Purchased without a prescription, these tests are simple and can be performed by a woman in the privacy of the home. One third of females who suspect they may be pregnant use home kits.[173] Most kits provide a single test and use an enzyme immunometric or immunochromatographic strategy to measure urine CG. Butler et al[56] have evaluated 15 home pregnancy tests. Detection limits vary from 6.3 to 50 IU/L,[56] although the manufacturers' claims vary from 25 to 100 IU/L. The tests require from 1 to 5 minutes to perform. Some poorly detect H-CG (ITA), which makes them less sensitive tests of early pregnancy.

Although the techniques used are straightforward, consumers do make more mistakes performing these tests than do trained laboratory professionals.[164] An extensive evaluation[102] of the commercial use of home test kits in France revealed that only 11 of 27 home-use tests performed by experienced technologists were as accurate as claimed. When the 11 tests were further evaluated by a group of female lay individuals, the clinical specificity ranged from 77% to 100% and the clinical sensitivity ranged from 31% to 100% even with samples at two times the claimed detection limit of the test. The high number of false-negative results was attributed to difficulty understanding the literature that accompanied the test. In the United States, the FDA has established guidelines evaluating manufacturers' submissions of home test pregnancy kits for approval.

First-morning specimens are preferred for qualitative point-of-care urine pregnancy tests because they are con-

centrated and contain abundant CG. Almost all tests use immunochromatography. Urine applied to the device is absorbed into a nitrocellulose bed. The CG is concentrated into a narrow band as the urine migrates. A dye-labeled anti-CG antibody in the device binds to the migrating CG and passes through a zone having solid phase capture antibody to CG. The appearance of a colored line indicates a positive test. Positive controls are usually an integral component of these devices—immobilized CG works well. Falsely positive results occur in 1% of tests because of the presence in urine of interfering substances such as proteins, drugs, bacteria, erythrocytes, or leukocytes. False-negative results can occur because some tests do not detect CG below 100 IU/L, even though most claim a detection limit below this concentration.[76] About half of these qualitative tests will be positive on the day after the first missed menstrual period. Denaturation of the CG antiserum caused by high temperature, pH extremes, or old reagents may also yield false-negative results. The simplicity and speed with which the results are obtained make these tests valuable for pregnancy confirmation, but they may miss the diagnosis of a very early or abnormal pregnancy. Qualitative *serum* assays are available and tend to be more reliable than urine assays, because urine CG concentrations can vary considerably.

Quantitative Laboratory Test Kits

Serum is used for quantitative CG assays. Blood specimens are collected into suitable tubes without anticoagulants, allowed to clot at room temperature, and centrifuged to obtain clear serum. If testing is to be delayed beyond 1 week, serum should be stored at −20 °C. As with most biological materials, repeated freezing and thawing of the specimen should be avoided. Serum specimens showing gross hemolysis, gross lipemia, or turbidity may give false results. Cole and Kardana[74] describe the five common strategies for measuring CG among 10 CG immunoassays: anti-CGβ RIA, anti-CGβ : anti-CGβ sandwich, anti-CGβ : anti-CGα sandwich, anti-CGβ C terminal : anti-CGβ sandwich, and anti-CG : anti-CGβ sandwich. The sandwich techniques used either immunoradiometric assay (IRMA) or immunoenzymometric assay (IEMA) for detection of CG. The specificity of quantitative serum assays varies considerably.[72] Most of the differences are attributed to differences in antibody recognition of the various forms of CG, nicked, β-subunit, H-CG, and other fragments present in serum. The lowest detectable concentration of these assays is 1 to 2 IU/L. Typical between-run imprecision (CV) is 10% to 15% at 10 IU/L, 6% to 15% at 30 IU/L, and 7 to 12% at 150 IU/L.[243]

Assay Methods for Second Trimester Screening

Almost all commercially available CG kits are high-sensitivity assays designed to measure concentrations from 2 to 1000 IU/L. Consequently, existing CG assays can be used for second trimester screening without modification. It is only necessary for laboratories to select an appropriate serum dilution so that measurements fall within the range of the calibration curve. A serum dilution of 1 : 200 to 1 : 500 is suitable for most assays. The vast majority of prenatal screening laboratories use automated immunometric assays for measuring CG. Such assays are available from Abbott Laboratories (Abbott Park, Ill.), Bayer (Medfield, Mass.), Beckman Coulter (Fullerton, Calif.), Diagnostic Products (Los Angeles), and Perkin Elmer (Norwalk, Conn.).

Calibrating CG Assays

Calibration of CG assays depends on standardized reference materials provided by the World Health Organization (WHO). The first material was released in 1938 by WHO and was designated the First International Standard (1st IS). This crude urine preparation was highly contaminated with biologically inactive CG fragments. In 1964, WHO released a product with higher potency, the Second International Standard (2nd IS, 61/6). Although the 2nd IS had higher biological activity per weight of protein, it too was contaminated with biologically inactive hormone. In addition, it also contained CGβ that reacted in some but not all immunoassays for CG. In 1978, WHO released the First International Reference Preparation (1st IRP, 75/537) of CG from the highly pure National Institutes of Health preparation, CR119. To avoid confusion, the 1st IRP was later renamed the Third International Standard (3rd IS). WHO released the 4th IS (75/589) in 1999, which is essentially identical to the 3rd IS. Results obtained from methods calibrated to each of these materials are not the same and cannot be directly compared. On a weight basis, the 2nd IS has about half the biological potency of the 3rd IS. Thus 160 ng of the 2nd IS has the same activity (1 IU) as 80 ng of the 3rd IS. Therefore tests calibrated against the 2nd IS have approximately half the value (in international units per liter [IU/L]) of tests calibrated against the 3rd IS. Most CG immunoassays are calibrated against the 3rd IS. Nonetheless, many of the CG results reported in the literature since 1972 are based on assays calibrated to the 2nd IS.

Because the 3rd and 4th IS contain about 5% nicked CG and other CG contaminants, highly pure CG materials have been prepared.[42] These preparations are designated *reference reagents* (RR) and contain CG (99/688), CGn (99/642), CGβ (99/650), CGβn (99/692), CGβcf, and CGα (99/720). The impact of using RR for assay calibration and harmonization is under study.

In spite of a common calibrator, assays calibrated using the 1st IRP/3rd IS still yield significant differences in CG values on the same specimens.[81] Therefore CG median values calculated for second trimester serum screening are not transferable and should be considered method-specific. CG measurements in early pregnancy are generally expressed as IU/L or international units per milliliter. A typical CG concentration at 16 weeks is approximately 30,000 IU/L, and many screening laboratories express CG concentrations in international units per milliliter (e.g., 30,000 IU/L is

expressed as 30 IU/mL) (see Figure 54-8). A simple alternative is to use kilo-international units per liter, consistent with the international system for SI units, in which concentrations are expressed per liter.

Specimen Collection and Handling

Serum specimens can be obtained from fasting or nonfasting women by standard phlebotomy techniques. CG is stable in maternal serum and can be shipped at ambient temperature and stored at 4 °C to 8 °C for 1 week.[152]

Specificity of CG Assays

Modern CG immunoassays should have little or no cross-reactivity with LH. Testing of serum samples with high physiological LH concentrations can be used to ascertain that this hormone does not significantly influence the CG results. Serum from postmenopausal women is a convenient source of specimens with high LH. The assay should be designed so that low concentrations of CG are detected and false-positive values caused by LH interference are minimized.

Clinical Significance

Measurement of CG can assist in the diagnosis and dating of pregnancy, identifying ectopic pregnancies and other abnormalities, managing certain neoplasms, and predicting the risk of Down syndrome and trisomy 18. Each of these clinical uses was discussed earlier in this chapter. Typical values during pregnancy are shown in Figure 54-3.

Alpha Fetoprotein

Measurement of AFP in maternal serum and amniotic fluid is used extensively throughout the United States and the United Kingdom for prenatal detection of some serious fetal anomalies. Use of AFP in nonpregnant patients for monitoring certain cancers is described in Chapter 23.

Chemistry

A fetal protein having α-electrophoretic motility was discovered in 1956 by Bergstrand and Czar.[35] Gitlan subsequently named this substance *α-fetoprotein.*[195] This glycoprotein has a molecular weight of ~70,000. The gene, located within q11-22 on chromosome 4, is part of a family of genes that also codes for albumin and vitamin D–binding protein (also called group-specific component and Gc globulin).[159] The protein is composed of carbohydrate and a single polypeptide chain containing 591 amino acids. The complete amino acid sequence has been determined.[136] The carbohydrate composition varies depending on the organ of synthesis, length of gestation, and source of the specimen (fetal serum versus amniotic fluid),[100] Although determination of the carbohydrate content does not appear to be useful diagnostically in the setting of pregnancy, it may be useful in the diagnosis of hepatocellular carcinoma.[266] The heterogeneity can be demonstrated by electrophoresis and dissimilar binding to various lectins, such as concanavalin A.

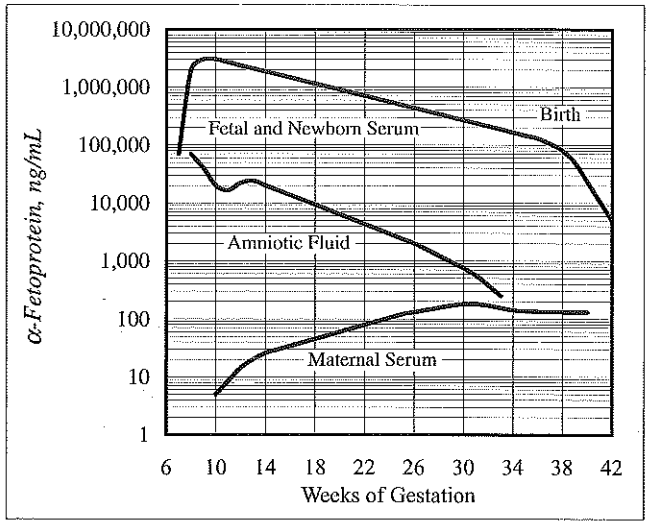

Figure 54-12 Concentrations of alpha fetoprotein (AFP) in fetal and newborn serum, maternal serum, and amniotic fluid. The maternal serum values are medians calculated from 24,232 pregnancies and the amniotic fluid values are medians calculated from 1544 pregnancies from testing performed at ARUP Laboratories Inc. from January to October 1997. The fetal serum values are from Gitlan.[137] The newborn serum values are from Wu et al.[349]

Biochemistry

AFP is produced initially by the fetal yolk sac in small quantities and then in larger quantities by the fetal liver as the yolk sac degenerates. Trace amounts are also produced in the fetal gut and kidneys. Early in embryonic life, this protein has a high concentration in fetal serum, reaching about one tenth the concentration of albumin. Maximal concentration in the fetal serum, approximately 3 million μg/L, is reached at about 9 weeks gestation. The concentration then declines steadily to about 20,000 μg/L at term (Figure 54-12).[137] The increase and decrease in concentration of AFP in the amniotic fluid roughly parallel those in the fetal serum but the concentration is two to three orders of magnitude lower (~15,000 μg/L at 16 weeks gestation). The relationship with respect to maternal serum concentration is slightly more complicated because of several factors, including fetal-maternal transfer, the rapid growth of the fetus, the relatively constant size of the mother, the maternal clearance of the protein, and variation of the volume of distribution in the mother with maternal weight. AFP is first detectable (~5 μg/L) in maternal serum at about the 10th week of gestation. The concentration increases about 15% per week to a peak of approximately 180 μg/L at about 25 weeks. A typical 16-week concentration is approximately 35 μg/L (see Figure 54-6).[150] The concentration in maternal serum then subsequently declines slowly until term. After birth, the maternal serum AFP rapidly decreases to less than 2 μg/L. In an infant, serum AFP declines exponentially to reach adult concentrations by the 10th month of life.[349]

The distribution of serum AFP concentrations in a population of pregnant mothers is Gaussian after logarithmic transformation.[330] Factors that affect the concentration of AFP in maternal serum include gestational age, maternal weight, the presence of insulin-dependent maternal diabetes mellitus, maternal race, the number of fetuses present, fetal renal disorders that cause proteinuria, and fetal structural anomalies.

Amniotic fluid AFP has been measured as early as 8 weeks.[341] It rapidly decreases to its lowest point at 11 weeks, then increases to reach a second maximum at 13 weeks. The concentration then falls in a log-linear fashion until 25 weeks, when the decline steepens. Several studies have shown that AChE used in combination with amniotic fluid AFP can aid in the detection of open neural tube defects from 13 to 25 weeks of pregnancy.[84]

Methods for Determining Alpha Fetoprotein

Although AFP was traditionally measured by RIA, newer methods use IEMA or chemiluminescent immunoassay (CIA) because of their lower detection limits, better precision, speed, avoidance of radioactivity, and ease of automation.[43] Most laboratories in the United States measure AFP by use of automated systems available from Abbott Laboratories (Abbott Park, Ill.), Bayer (Medfield, Mass.), Beckman Coulter (Fullerton, Calif.), Diagnostic Products (Los Angeles), and Perkin Elmer (Norwalk, Conn.). Judging from the results of proficiency testing sponsored by the Foundation for Blood Research and College of American Pathologists (Survey FP), all of these systems perform satisfactorily.[81]

Calibration

Although two essentially equivalent international standards (WHO Reference Preparation for AFP [72-225] and British Standard [72-227])—both calibrated in international units—are available, most laboratories in the United States report AFP in nanograms per milliliter (i.e., micrograms per liter). The relationship between nanograms and international units usually is given as 1.21 ng = 1 IU, but conversion factors may vary by manufacturer, perhaps reflecting differences in the carbohydrate content of the respective calibrators.[152]

Specimen Collection and Handling

Serum specimens can be obtained from nonfasting women by standard phlebotomy techniques. AFP is very stable in maternal serum and can be shipped at ambient temperature and stored at 4 °C to 8 °C for 1 week or at −20 °C for years.[152]

Clinical Significance

Maternal serum and amniotic fluid AFP are useful tests for detecting some serious fetal anomalies. Maternal serum AFP is elevated in 85% to 95% of cases of fetal open neural tube defect[330] and is low in about 30% of cases of fetal Down syndrome.[91,217] Because maternal serum screening for fetal defects involves multiple tests, this subject was discussed earlier under Maternal Serum Screening for Fetal Defects.

Measuring Amniotic Fluid Alpha Fetoprotein

Amniotic fluid AFP is measured using the same immunoassays as for maternal serum AFP after a suitable dilution (usually 1:50 to 1:200). Results can be expressed in micrograms per milliliter, micrograms per liter, or kilo IU per liter, and most laboratories use mass units. AFP in amniotic fluid is less stable than in serum. Leaving samples at room temperature for prolonged periods, such as might occur during processing for chromosome analysis, can result in degradation of amniotic fluid AFP. Refrigeration of amniotic fluid can compromise the chromosome analysis. Therefore a portion of the collected fluid should be placed in the refrigerator as soon as possible after collection. Samples sent to reference labs can be shipped for next day delivery at ambient temperature or on ice packs if the outside temperature is high. The presence of fetal blood in amniotic fluid samples can increase AFP results, and laboratories should note the presence of blood on the report. In the event of an increased amniotic fluid AFP result (usually above 2.0 or 2.5 MoM), the laboratory should test for the presence of fetal blood. Laboratories that measure amniotic fluid AFP need to establish medians for each week between 13 and 25 weeks of gestation. A method has been published that allows extrapolation to 13 weeks using data from 14 to 25 weeks.[250] Medians from ARUP Laboratories Inc. (Salt Lake City) are shown graphically in Figure 54-12.

Measuring Amniotic Fluid Acetylcholinesterase

AChE is an essential confirmatory test for all fluids with elevated amniotic fluid AFP. Normal amniotic fluid contains a group of nonspecific cholinesterases referred to as pseudocholinesterase (PChE). Cerebrospinal fluid contains high concentrations of the neural enzyme AChE, and in cases of fetal open neural tube defects (and in about 80% of cases with defects of the abdominal wall), fluid leaks from the open lesion and allows AChE to enter the amniotic fluid.

The usual technique for identification of AChE is fractionation by polyacrylamide gel electrophoresis followed by incubation of the gel with the substrate acetylcholine and copper ions. AChE migrates more rapidly than PChE and appears as a distinct white precipitate band below the PChE band. That the second band is AChE is documented by inhibition of the enzyme activity in the band by the specific AChE inhibitor 1,5-bis(4-allyldimethylammoniumphenyl) pentan-3-one dibromide—BW284C51. No method is available commercially; laboratories develop their own assay systems using published methodology.[51,148] Enzyme immunoassay using a monoclonal antibody specific for neurally derived AChE has also been used.[239]

Unconjugated Estriol

Measurement of urinary and serum estriol (E_3), once used to assess fetal well-being, is no longer recommended for that

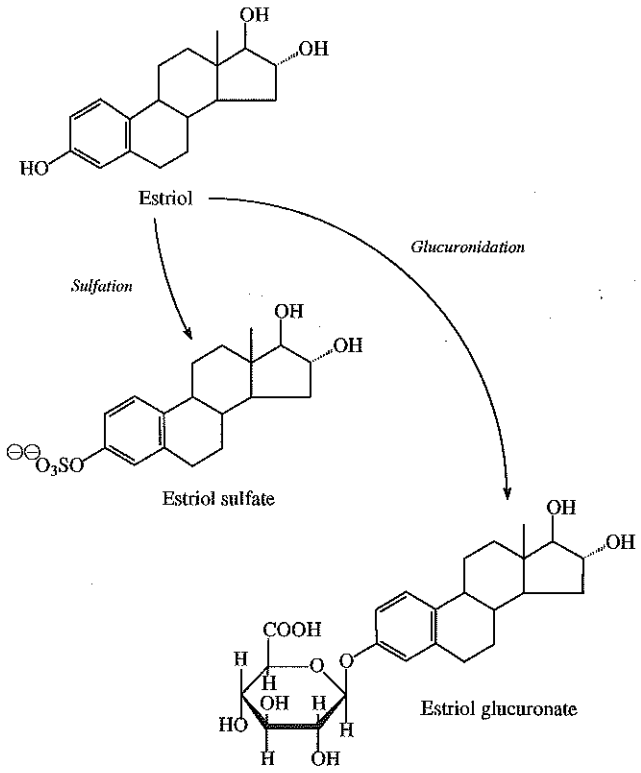

Figure 54-13 The forms of estriol present in maternal serum. Glucuronidation and sulfation can also occur at the other hydroxyl positions.

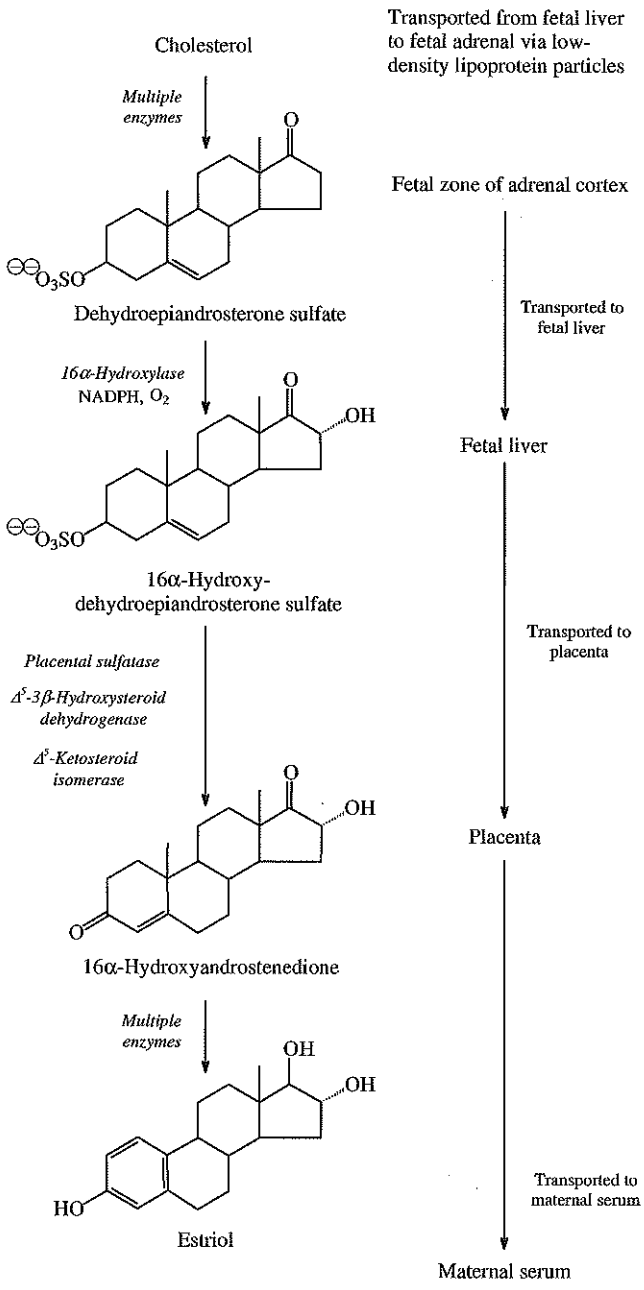

Figure 54-14 The biosynthetic pathway for estriol during pregnancy.

purpose.[93] Measurement of unconjugated estriol (uE_3) is now used routinely by most United States laboratories that provide screening for Down syndrome. This steroid, rather than total estriol (unconjugated plus conjugated estriol), is the most specific of the estrogens for identifying a fetus with Down syndrome.

Chemistry

Estriol, as its name implies, is an estrogen with three hydroxyl groups (at positions 3, 16, and 17). Its systematic name is 1,3,5(10)-estriene-3,16-α,17-β-triol. Although present in nonpregnant patients in very low concentrations, during late pregnancy this estrogen predominates. Only a minor amount (~9%) of the hormone circulates in plasma unconjugated and, because of its low solubility, this form is strongly bound to SHBG. The majority exists as conjugates of glucuronate and sulfate (Figure 54-13). The conjugation occurs in the maternal liver, makes the hormone more soluble and, thus, permits renal clearance.

Biochemistry

Estriol is produced in very large amounts during the last trimester of pregnancy. The biosynthetic pathway requires three organs to be fully functioning: fetal adrenal, fetal liver, and placenta (Figure 54-14). The fetal adrenal cortex possesses a unique zone for the production of steroids. The demand for estriol is so great that the fetal adrenal is massive compared with that of an adult. The fetal zone accounts for approximately 80% of the adrenal weight. The fetal adrenal avidly binds low-density lipoprotein to take in cholesterol, which is converted to two major steroid intermediates: pregnenolone sulfate and dehydroepiandrosterone sulfate (DHEAS). These intermediates are secreted into the fetal circulation. The fetal liver, possessing 16α-hydroxylase, converts DHEAS to 16α-hydroxy-DHEAS, which is secreted back into the fetal circulation. Finally the placenta synthesizes estriol from 16α-hydroxy-DHEAS. Approximately 90% of maternal serum estriol is derived from this pathway. A

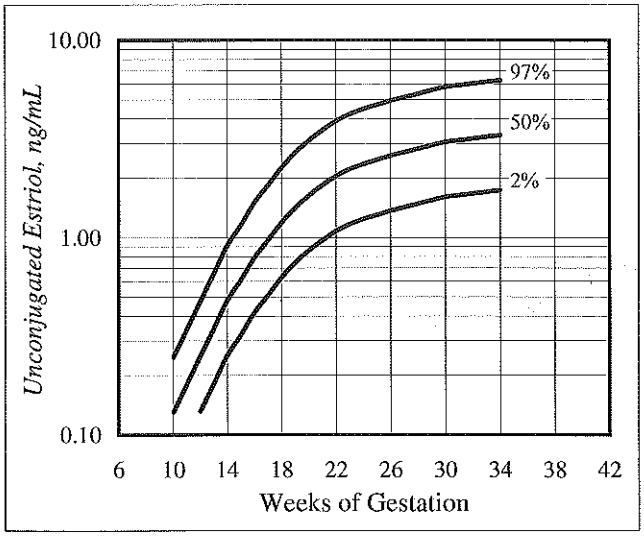

Figure 54-15 Concentration of unconjugated estriol (uE_3) in maternal serum as a function of gestational age. Lines represent the 2nd, 50th, and 97th percentiles. The maternal serum values from 14 to 25 weeks are medians calculated from 11,309 pregnancies from testing performed at ARUP Laboratories Inc. from January to October 1997.

minor amount is made using precursors from the maternal ovary. The relationship of maternal serum uE_3 to gestational age in the second trimester is log-linear, increasing at a rate of 20% to 25% per gestational week[150] (Figure 54-15). The concentrations typical for the second trimester of pregnancy are 0.70 to 2.50 µg/L, depending on the assay used. Serum concentrations of estriol conjugates are fivefold to tenfold higher than serum concentrations of uE_3 during pregnancy.

Methods for Determining Unconjugated Estriol

Concentrations of estrone, estriol-3-sulfate, and estriol-3-glucuronide up to 1000 ng/mL cross-react less than 0.03% in current assays.

The determination of uE_3 is made difficult by its low concentration. Until 2002, uE_3 was measured by ultrasensitive RIA methods (primarily the assay available from Diagnostic Systems Laboratories [DSL, Webster, Tex.]) that have been clinically validated extensively by case-control and intervention studies. More recently, nonisotopic assays have become available, usually as part of automated systems. The correlation between these methods and the RIA methods is generally low, ($r^2 \sim 0.8$), and most have not been clinically validated. Many laboratories have switched to nonisotopic methods because of the convenience of a common platform for measuring uE_3 and other screening tests. Ideally, screening laboratories should not use these nonisotopic assays until they have been clinically validated using known cases of Down syndrome and unaffected pregnancies or they have shown good agreement with validated assays after conversion to MoM. A recent publication shows that the nonisotopic method manufactured by Beckman Coulter (Fullerton, Calif.) yields screening performance that is equivalent to a previously validated RIA.[209] Other nonisotopic assays are available from Bayer (Medfield, Mass.), Diagnostic Products (Los Angeles), and Perkin Elmer (Norwalk, Conn.). Values obtained with the various uE_3 assays vary widely as judged using the Foundation for Blood Research/CAP proficiency testing Survey FP.[81] Conversion to MoM reduces the between-method differences, but uE_3 is still the most variable of the screening analytes.

Calibration

Assays for uE_3 are calibrated by use of chemically pure estriol. Estriol values can be reported in mass units (nanograms per milliliter or micrograms per liter) or SI units (nanomoles per liter). The equation for converting mass to SI units is 1 nmol/L = 3.47 ng/mL = 3.47 µg/L. Although pure uE_3 is available for calibrating uE_3 assays, commercial kits yield values on clinical specimens that can differ by factors of 2 to 3.

Specimen Collection and Handling

Maternal serum specimens can be obtained from nonfasting women by standard phlebotomy techniques. uE_3 is the least stable of the four analytes currently used for screening, and consequently, requirements for collection, storage, and shipment are dictated by this analyte. The uE_3 concentration increases in blood at room temperature and at 4 °C, because the conjugated forms can spontaneously deconjugate to form the parent hormone.[152] Therefore collected blood should be allowed to clot and then serum should be removed promptly. If serum separator tubes are used, specimens should be centrifuged promptly after collection. Shipment of whole blood is not preferred. If whole blood is shipped through the mail, next day delivery is essential. uE_3 is stable in serum for up to 7 days at 2 °C to 4 °C (unpublished data, Foundation for Blood Research, Woman and Infant's Hospital, and ARUP Laboratories). The concentration of uE_3 increases when sera have been stored for more than 4 days at room temperature.

Clinical Significance

Any disruption in the biosynthetic pathway will lead to very low maternal serum uE_3. Conditions that cause disruption include fetal anencephaly, placental sulfatase deficiency, fetal death, chromosome abnormalities, molar pregnancy, and Smith-Lemlit Opitz syndrome (SLOS).[47,314] Placental sulfatase deficiency presents in the infant as X-linked ichthyosis. It is present in approximately 1 in every 2000 males. Because of the lack of uE_3, the mother often has delayed onset of labor. The cesarean section rate is significantly higher in these mothers. SLOS is a serious, rare birth defect that is the result of an inborn error in cholesterol metabolism, 7-dehydrosterol-7-reductase deficiency. Down syndrome leads to a modest decrease in uE_3. Screening for Down syndrome is now the most common application of uE_3 measurements.[332]

DIMERIC INHIBIN A

Inhibins are members of the transforming growth factor β (TGFβ) superfamily of proteins. Inhibin forms include inhibin A and B, and activin A, B, and AB. As described in Chapter 53, inhibin is a negative feedback regulator of FSH secretion in both males and females. The placenta produces large quantities of inhibin A that completely suppress FSH.

Chemistry

Inhibins are proteins consisting of dimers of dissimilar subunits (α and β) linked by disulfide bridges (Table 28-1). The β-subunit occurs in two closely related forms (β_A and β_B), leading to two types of dimeric inhibin (dimeric inhibin A, $\alpha\beta_A$ and dimeric inhibin B, $\alpha\beta_B$). The mature form of inhibin, which has a molecular mass of approximately 30,000, is produced by cleavage of larger precursor forms. Precursor forms are relatively less bioactive than the mature forms. In follicular fluid and serum, mature inhibins, precursors of inhibins (particularly the processed form of the free α-subunit, pro-αC), and intermediate molecules of varying molecular weight are present.[312] Another group of related molecules, the activins, are dimers consisting of just the β-subunits. They are also found in biological fluids. Of the two forms of inhibin and the many related molecules found in serum, only DIA has been shown to provide sufficient discrimination to be useful for Down syndrome screening.[194]

Biochemistry

Inhibins, and the closely related activins, are proteins that suppress or stimulate follicle-stimulating hormone secretion. Inhibins are secreted by granulosa cells of the ovary and by the Sertoli cells of the testis. Inhibin A and inhibin B have distinctive profiles during the human menstrual cycle. Inhibin A rises from 10 to 20 ng/L in the follicular phase of pregnancy to a maximum of 40 to 60 ng/L. Inhibin B is maximal in the midfollicular phase, with a peak at ovulation (about 60 ng/L) before decreasing to basal levels in the luteal phase. In postmenopausal women, the concentrations of both forms of inhibin are below 5 ng/L.[207] Men secrete inhibin B, but do not appear to produce inhibin A. Inhibin A is produced by the fetoplacental unit beginning in early pregnancy. DIA concentrations exhibit a complex pattern during the course of pregnancy, rising to a peak at 8 to 10 weeks of gestation, declining to a minimum at 17 weeks of pregnancy, and then resuming to slowly increase at term (see Figure 54-9). Unlike the other screening tests, average inhibin levels change relatively little from 15 to 20 weeks gestation. A typical value at 17 weeks gestation is 175 ng/L (175 pg/mL).

Assay Methods for DIA

Inhibin assays used for Down syndrome screening must measure only dimeric inhibin A and not the free α-subunits and the precursors of higher molecular weight, which also circulate in blood. The original inhibin assays (ELISA or RIA) used antibodies directed against epitopes on the α-subunit and measured all forms of inhibin, including precursors. These assays are referred to as total inhibin or immunoreactive inhibin assays. Highly specific assays using monoclonal antibodies are available that measure only dimeric inhibin A. Specific DIA assays provide better screening performance than the nonspecific total inhibin assays.[194] The widely used DIA method from Diagnostic Systems Laboratories (Webster, Tex.) has been clinically validated[185] and performs well in the Foundation for Blood Research/College of American Pathologists Maternal Survey FP.[81]

Typical values in the second trimester of pregnancy range from 50 to 400 pg/mL (50 to 400 ng/L), as shown in Figure 54-9.

Specimen and Sampling Handling

Serum specimens can be obtained from nonfasting women by standard phlebotomy techniques. DIA is stable in maternal serum and can be shipped at ambient temperature and stored at 4 °C to 8 °C for 1 week.

Clinical Significance

In addition to the usefulness of DIA as a predictor of Down syndrome risk discussed previously, inhibin A and B measurements have found applications in ovarian cancer monitoring, disorders of ovulation, early detection of viable pregnancy following in vitro fertilization, and evaluation of male infertility.[194,272]

FETAL FIBRONECTIN

Determining the risk of preterm labor would help clinicians manage those at high risk more aggressively and thereby lower the incidence of preterm delivery. In 1991, fetal fibronectin concentration in cervical and vaginal secretions was proposed as a test to aid in predicting preterm delivery.[206]

Fibronectin is a term for a family of ubiquitous adhesive glycoproteins that cross-link to collagen to bind cells together. These proteins are found on cell surfaces and in plasma and amniotic fluid. The fetus has a unique fibronectin that is defined by a monoclonal antibody, FDC-6, which recognizes the epitope defined by α-*N*-acetylgalactosamine linked to threonine in a hexapeptide sequence (Val-Thr-His-Pro-Gly-Tyr), the IIICS domain.[213] When labor begins and the cellular adhesion between the placenta and the uterine wall is disrupted, the concentration of fetal fibronectin in cervical and vaginal secretions increases. Mothers with more than 50 ng/mL (50 μg/L) of fetal fibronectin in these secretions during the second and third trimesters have a higher risk for preterm delivery. The majority of patients with results >50 ng/mL will, however, repair any placental disruption and successfully continue the pregnancy.[141]

Assay Method

In the past, Adeza Biomedical Corp. (Sunnyvale, Calif.) offered an enzyme-linked immunosorbent assay (ELISA) for fetal fibronectin that used a 96-well microtiter plate format and took 2 hours to complete. In 1995 the FDA approved the use of this test in symptomatic women; in 1997 screening asymptomatic women was approved. Currently, two rapid tests are available. The one that is available in the United States is a membrane immunoassay, using a solid phase polyclonal goat anti-fFN antibody and an enzyme-labeled monoclonal anti-fFN, FDC-6 detection antibody. The specimen is obtained by collecting cervical or vaginal mucus with a Dacron polyester swab. The fully saturated swab contains approximately 150 µL of fluid. The swab is placed into 750 µL of buffer, creating a 1:5 dilution. An aliquot of the specimen is added to the cassette containing the antibodies. The color development is measured using the Adeza TLi_{IQ}^{TM} analyzer.

Asymptomatic Patients

In screening asymptomatic women, testing should take place sometime between 24 and 30 weeks gestation. Women with a positive result (>50 ng/mL) are at a twofold to fourfold higher risk for preterm delivery. A negative test following a positive test lowers the risk, and a second subsequent negative test returns the risk to baseline.[141] Among asymptomatic women, positive fFN results have a likelihood ratio of 4.01 (95% confidence interval 2.93 to 5.49) for predicting birth before 34 weeks' gestation. For negative fFN results, the corresponding likelihood ratio is 0.78 (0.72 to 0.84).[167]

Symptomatic Patients

The symptoms of preterm labor include regular uterine contractions, low back pain, lower abdominal cramping, and vaginal bleeding and increased vaginal discharge. Among symptomatic women, positive fFN results have a likelihood ratio of 5.42 (95% confidence interval 4.36 to 6.74) for predicting delivery before 34 weeks' gestation or within the next 7 days. For negative fFN results, the corresponding likelihood ratio is 0.25 (0.20 to 0.31).[167] Those patients with a negative test can safely return home, because they have only a ~1% chance of delivering in 1 week.[254]

Amniotic Fluid Bilirubin (ΔA_{450})[201]

The concentration of bilirubin in amniotic fluid is generally too low (~0.01 to 0.03 mg/dL; 0.17 to 0.51 µmol/L) to be measured by standard photometric techniques, but the determination can be done rapidly, accurately, and directly by absorption spectrophotometry. The maximal absorbance of bilirubin is at 450 nm. In the absence of significant amounts of bilirubin, the absorbance spectrum for the amniotic fluid between 365 and 550 nm defines a nearly exponential curve (Figure 54-16). On log-linear axes, the height of the curve at 450 nm above the straight line is linearly proportional to the concentration of bilirubin in the amniotic fluid. This is the difference in absorbance at 450 nm (ΔA_{450}), which is still occasionally referred to as ΔOD_{450} in the clinical literature. There is normally a small amount of bilirubin in amniotic fluid, and this amount changes with gestational age (Figure 54-17). To interpret properly the ΔA_{450}, it is necessary to know the gestational age. The procedural details are available on the Evolve site that accompanies this book.

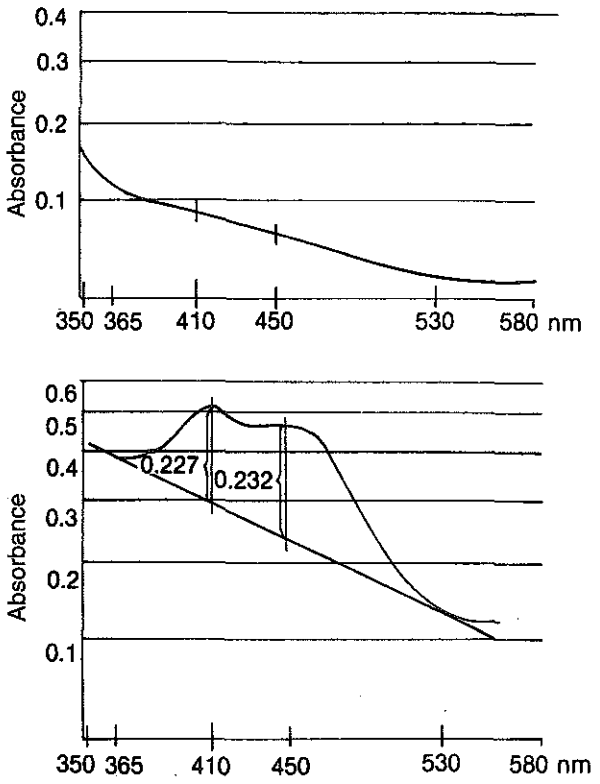

Figure 54-16 A, Normal amniotic fluid. Note near linearity of the curve when plotted on log-linear graph. **B,** Amniotic fluid showing the bilirubin peak at 450 nm and the oxyhemoglobin peak at approximately 410 nm. Note the baseline drawn between linear parts of the curve, from 530 and 365 nm.

Interpretation

Interpretation of ΔA_{450} depends on knowing the gestational age of the pregnancy (see Figure 54-17). Values that fall into Liley's bottom zone (Figure 54-17) are considered to represent an unaffected or very mildly affected fetus. Values in the middle zone are still compatible with a minimally affected fetus, but as values rise within this zone, it is increasingly likely that a fetus is suffering moderate to marked hemolysis. Depending on the trend with time and the clinical circumstances, some clinicians recommend intervention when ΔA_{450} has climbed 85% up in the middle zone. Values in the top zone (zone III) denote severe disease. Without intervention, a fetus with values in the top zone will most likely die.[201]

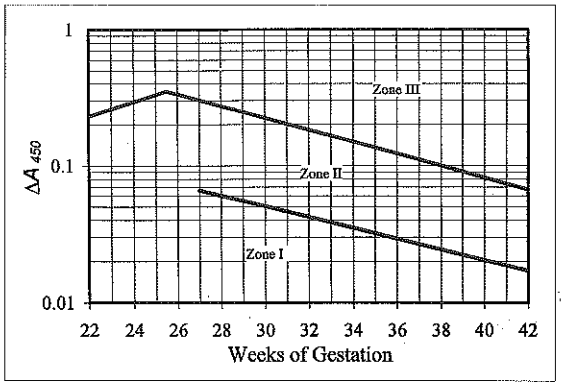

Figure 54-17 Liley's three-zone chart (with modification) for interpretation of amniotic fluid ΔA_{450}. For explanation of the three zones, see text. *(Modified from Liley AW. Liquor amnii analysis in the management of the pregnancy complicated by rhesus sensitization. Am J Obstet Gynecol 1961;82:1359-70.)*

Contamination of an amniotic fluid specimen with fetal blood from an affected fetus with a high serum bilirubin level could introduce a substantial error, the magnitude of which cannot accurately be predicted. Blood contamination of amniotic fluid should be obvious from the red color and the presence of erythrocytes in the pellet after centrifugation. It is important to minimize hemolysis of the erythrocytes in such samples (by rapid processing) as the hemoglobin will interfere in the test. A Kleihauer-Betke (or other) test should be performed on the erythrocytes to establish their origin. The Kleihauer-Betke test uses an acid solution to elute the hemoglobin A, but not hemoglobin F, from erythrocytes fixed on a glass slide. Thus under microscopic examination, maternal cells appear as ghosts, and fetal cells appear red. If the erythrocytes are largely fetal, this should be kept in mind when interpreting the fluid results. If the amniotic fluid remaining within the amniotic cavity has been contaminated with blood by traumatic amniocentesis, these erythrocytes lyse and contaminate the fluid with hemoglobin and bilirubinoid pigments. It takes 2 to 3 weeks for these pigments to be cleared and for the fluid to return to the original state. Both mathematical corrections and choloform extraction can be used for bloody specimens (see the Evolve site that accompanies this book).[127]

In a pregnancy with twins within separate sacs, the individual sacs must be sampled. Inadvertent sampling of maternal urine is always a possibility,[202] although the risk of this error is reduced when using ultrasonography.

Occasionally, during monitoring of a sensitized pregnancy, delivery seems imminent and a large dose of glucocorticoids is administered to stimulate fetal lung maturation. If the patient is not delivered and if amniocentesis is repeated within 2 to 4 days of the steroid course, the ΔA_{450} is lowered relative to the level found immediately before the steroid administration.[63] Further observation and amniocenteses show that the ΔA_{450} returns to the previous level or higher within a week. It seems doubtful that this phenomenon represents a decrease in hemolysis; instead, it may be an artifact, possibly caused by acute changes in amniotic fluid volume.

Meconium staining of amniotic fluid increases the ΔA_{450} with a broad and variable peak at 400 to 415 nm.[202] There is no way to compensate quantitatively for meconium contamination. Clearance of meconium from a single episode of passage into the amniotic fluid requires about 3 weeks.

Tests for Evaluating Fetal Lung Maturity

Fetal lung maturity (FLM) tests help a clinician decide whether the best perinatal survival will be achieved in utero or in the nursery. The most common situation in which a fetal lung maturity test is ordered is before repeat cesarean delivery when the age of gestation is somewhat uncertain. Another major indication is anticipated early delivery because of some medical or obstetrical indication, such as preterm labor, premature rupture of the membranes, worsening maternal hypertension, severe renal disease, intrauterine growth retardation, or fetal distress. Results indicating immaturity of the fetal lungs might cause postponement of elective delivery or prompt active intervention with tocolytics to suppress preterm labor. Pharmacological administration of corticosteroids before birth accelerates pulmonary maturation and can prevent RDS.[4] If delivery of an infant is inevitable, transfer to a tertiary health care center is appropriate.

Numerous tests of amniotic fluid for FLM have been proposed.[216] Some of these, such as creatinine determination,[101] urea measurement,[2] or the lipid staining characteristics of cells, correlate with gestational age but do not measure lung maturation. Tests that measure lamellar bodies directly or indirectly, the surfactant they contain, or the biophysical property of surfactant are the most useful for evaluating FLM. Six methods that measure pulmonary surfactant are presented in detail: the lecithin/sphingomyelin (L/S) ratio, DSPC, phosphatidylglycerol, foam stability, fluorescence polarization (both commercial and noncommercial assays), and lamellar body counts. Since 1994, the CAP has offered a proficiency testing survey for FLM methods. Table 54-6 lists the number of laboratories that reported using each of the methods in recent surveys by the CAP. The number of laboratories performing methods requiring thin-layer chromatography (L/S ratio and phosphatidylglycerol) has decreased, while the number of laboratories using commercial fluorescence polarization has dramatically increased.

Other surfactant-based tests include those that measure turbidity at either 400 nm or 650 nm.[285,300] These tests measure the effect of light scattering by lamellar bodies suspended in the amniotic fluid. An absorbance greater than 0.15 at 650 nm is claimed to indicate lung maturity. Unfortunately, the absorbance of amniotic fluid is affected not only by light scattering but also by substances that absorb light. Use of these rapid techniques has been discouraged.[264] Dubin modified amniotic fluid absorbance by measuring the dif-

TABLE 54-6 Number of Laboratories Performing Fetal Lung Maturity Testing, by Method: College of American Pathologists Proficiency Testing Survey (2001-2004)

Method	Year			
	2001	2002	2003	2004
TDx FLM II	427	462	470	469
Phosphatidylglycerol (AmnioStat-FLM)	421	447	401	43*
Phosphatidylglycerol (thin-layer chromatography)	113	110	103	87
Lecithin/sphingomyelin ratio	142	138	122	97
Fluorescence polarization (NBD-PC)	10	9	7	9

*In late 2003 through 2004, Irvine Scientific was unable to provide AmnioStat-FLM reagents to laboratories.

ferential absorbance of amniotic fluid when mixed with water versus glycerol.[111] He coined the term refractive index-matched anomalous diffraction (RIMAD). This technique measures just the absorbance caused by light scattering and can be used to predict the particle density of the lamellar bodies. A prospective clinical outcome study reported that RIMAD has clinical sensitivity and specificity as good as fluorescence polarization.[274] Addition of as little as 25 μL of erythrocytes, however, causes significant interference.

Surfactant proteins (SP-A and SP-B) have been evaluated as potential fetal lung maturity tests, but the results are disappointing.[178,267]

The American College of Obstetricians and Gynecologists issued an educational bulletin on the assessment of fetal lung maturity in 1996.[5] Readers may want to carefully read that bulletin, because many obstetricians rely on it.

Standards of laboratory practice for FLM testing[20] have been published that make several recommendations regarding specimen collection, handling, centrifugation, and mixing. Hospital laboratories should offer a rapid test, such as fluorescence polarization, phosphatidylglycerol, or foam stability index (FSI). These should be available daily on both a routine and emergency basis. Requests for L/S ratios and lung profiles may be sent to a reference laboratory. Analysts should communicate the results of any FLM test immediately to the ordering location, because the patient's status may be changing and the information might assist with management of labor.

Collection and Handling of Amniotic Fluid for Fetal Lung Maturity Assessment

Before the details of individual methods are given, details of the specimen and specimen handling are described. These topics are common to many methods.

Specimen

Amniotic fluid is obtained by transabdominal amniocentesis usually during real-time sonographic visualization. The clinician should try to avoid traversing the placenta, but will sometimes fail. In a multifetal pregnancy, there are usually separate sacs. Each individual sac should be sampled. Fluid may be obtained by transvaginal puncture of the bulging membranes, but it should not be grossly contaminated with vaginal secretions as might occur with aspiration of a vaginal pool after spontaneous rupture of the membranes. Vaginal pool specimens are rarely adequate for testing. Clinicians should seriously consider amniocentesis in patients with ruptured membranes.[20] Bedside ultrasound examination will often locate a pocket of amniotic fluid that can be tapped without endangering the fetus.

Whenever possible, the fluid should be tested immediately. If there is to be a delay of a few hours, the fluid should be refrigerated at 4 °C.[287] The total phospholipid content of amniotic fluid does not change significantly during at least a week of storage.[324] If testing will be delayed longer than 1 week (e.g., fluids kept for research studies), fluids should be stored frozen at −20 °C or −70 °C. Immediately before testing the fluid, it should be gently inverted 20 times to obtain a uniform suspension. At least 2 minutes on a test tube rocker is recommended.[20]

Specimen Handling

Most procedures for measuring fetal lung maturity include a centrifugation step to remove debris. Careful attention to technique is needed to obtain reproducible results. Any centrifugation removes some pulmonary surfactant from the specimen. Accidentally prolonged centrifugation can reduce recovery of the phospholipids to less than 50%.[244] For best results, the specimen should be well mixed, lightly centrifuged, decanted, and mixed again.

1. Invert the amniocentesis collection tube 20 times or place it on a tube rocker for 2 to 5 minutes. Transfer the entire contents to a clear test tube.
2. Note the condition of the specimen: uncontaminated, bloody, meconium stained, xanthochromic, or obviously contaminated with mucus. Blood and meconium interfere with most tests. The report of the result should always list any contaminates seen.
3. For tests other than the Abbott fluorescence polarization method (which uses filtered fluid) and the lamellar body count, centrifuge the fluid for 2 minutes at 400 ×g.
4. Decant the supernatant into a new test tube.

Before transfer of any aliquot from the new tube, mix it well by inverting 20 times or placing it on a tube rocker for at least 2 minutes. When not mixing, keep the specimen on wet ice.

Fluorescence Polarization Fetal Lung Maturity Tests[26,125,309]

The TDx FLM II fluorescence polarization technique is the most commonly used quantitative method, as judged by enrollment in the CAP Fetal Lung Maturity proficiency test survey (see Table 54-6). This rapid test has better precision than the L/S ratio.[295] The test was originally described in 1976 by Shinitzky and colleagues, who used diphenylhexatriene (DPH) as the fluorescent dye. Although the DPH test is predictive of FLM, many laboratories had difficulty working with this dye, because it is an easily oxidized compound that absorbs UV light. The UV fluorescence polarimeter instrument, the FELMA, was difficult to maintain. These disadvantages prevented widespread use of DPH fluorescence polarization in clinical laboratories. Tait and associates[309] improved the technique by using a more stable fluorescent dye, NBD-PC, and a commercial polarimeter, the Abbott TDx. Russell[278] developed a commercial version of the assay using a slightly different dye, PC-16. The first generation TDx FLM was replaced with the second generation TDx FLM II in 1995. This transition lowered the results approximately 4%.[260]

The commercial version is calibrated with solutions containing phospholipid and albumin in various ratios, expressed as milligrams of surfactant per gram albumin. The vast majority of laboratories performing fluorescence polarization testing for FLM use the commercial version of the assay (see Table 54-6). The NBD-PC method is described on the Evolve site that accompanies this book for those laboratories that are willing to prepare the reagents and perform the calculations required for interpretation.

Fluorescence polarization is a dimensionless ratio with values from 0.000 to 0.500 for dilute solutions containing fluorescing compounds (see Chapter 3).[193] Polarization (P) measures the rotational diffusion of the fluorophore relative to its fluorescent half-life. If the half-life is short compared with the rate of rotational diffusion, P will be high. In contrast, if molecular rotation is faster than the excited state decay, then P will be low. Shinitzky proposed that for amniotic fluid, lower polarization values reflected a decrease in the microviscosity of surfactant phospholipids. The fluidity of these phospholipids paralleled the change in lipid composition with maturation of the fetal lungs.[295] This mechanism is incorrect for the NBD-PC method. NBD-PC binds to albumin and to surfactant; thus the resulting polarization is a function of the surfactant/albumin ratio.[22]

TDx FLM II Method

The commercial fluorescence polarization test, TDx FLM II (Abbott Laboratories, Abbott Park, Ill.), has an analytical measurement range of 0 to 160 mg surfactant/g albumin. Uncentrifuged amniotic fluid is used for this method. If specimens have been accidentally centrifuged, the surfactant can be resuspended before testing.[145] Approximately 1 mL of amniotic fluid is passed through a glass filter before testing on the TDx analyzer. The TDx FLM II assay uses 25 µL of filtered amniotic fluid. Imprecision (CV) is 4% to 5% at both 20 and 115 mg/g.

Although studies of the first-generation test[166,279,303,347] recommended a maturity cutoff of 70 mg phospholipid/g of albumin or greater, the second-generation decision limits are different; values less than or equal to 39 mg/g are considered immature, those greater than or equal to 55 mg/g mature, and others (40 to 54 mg/g) intermediate. Several clinical outcome studies of the first-generation test suggested that the upper cutoff could be lowered without impacting the sensitivity for RDS.[17,163,303] Similar studies of the TDx FLM II show that ≥45 mg/g can be used as a cut point, which will improve the assay specificity to 85% while maintaining sensitivity for clinically significant RDS at 95% to 100%.[119,182]

Several investigators have recommended that TDx FLM II be interpreted as a function of gestational age.[179,261] Instead of changing the decision limits for each gestational age, the authors recommend reporting the RDS risk for a given TDx FLM II result at a specific gestational age. The calculated risks, however, will vary with the tested population.[147] The outcome studies were conducted at tertiary hospitals that handle high-risk obstetrical cases. Thus use of these risk models is best restricted to those settings. If the risk calculations are used at hospitals that care for low-risk obstetrical populations, the risks are overestimated.

Most twins are delivered preterm and many suffer from preterm complications. If those complications are excluded, twins have the same RDS incidence as do singletons matched for gestational age.[132] After 31 weeks' gestation, however, the average TDx FLM II results from twin pregnancies are 22 mg/g higher than those from singleton pregnancies.[215] Sampling both sacs is recommended when testing before 32 weeks' gestation.[345]

Several studies have concluded that diabetes does not affect the reference values of TDx FLM II.[105,203]

NBD-PC Fluorescence Polarization Method

The NBD-PC method, also called FPol, is described in detail on the Evolve site that accompanies this book. The specimen is amniotic fluid that has been centrifuged at 400 ×g for 2 minutes. Results are expressed using artificial units of millipolarization (P × 1000, mP). The analytical measurement range is 150 to 350 mP. No calibrators are used, but use of a Triton ×100 control assures that the temperature is correct and that the dye is not degraded. Comparison of the TDx FLM II and the NBD-PC assay reveals, as expected, a strong nonlinear, inverse correlation:[21,24]

$$\text{TDx FLM II (in mg/g)} = -139.5 \ln(\text{FPol in mP}) + 817$$

An NBD-PC fluorescence polarization value of less than 260 mP is considered mature, values between 260 and 290 mP are considered transitional, and values greater than

290 are considered immature.[69,308] Using 260 mP as the cutoff, this test has a clinical sensitivity of 94% and a clinical specificity of 84%. The supplemental use of the L/S ratio for those patients with transitional results is of little benefit. The 260 mP cutoff is appropriate for high-risk pregnancies. In the setting of a patient who needs a cesarean section at term, when there is no penalty for delaying delivery, a cutoff of 230 mP is more appropriate.

If there is less than 0.5% blood in the amniotic fluid, the results are not affected. Contamination with more than this amount tends to increase low results and decrease high results.[309] Results that are clearly mature (<230 mP) or immature (>290 mP) are reliable for predicting fetal lung status. Results between these values cannot be interpreted.

Because of improved pregnancy management, very few infants with RDS are born to women with diabetes. Thus exact estimates of clinical sensitivity and specificity are not available in this clinical setting. The predictive value of a mature status in a patient with diabetes mellitus appears to be equivalent to that in a patient without diabetes.[69] The diabetes studies that used the commercial TDx FLM II test imply that diabetes mellitus does not affect the medical decision limit of NBD-PC fluorescence polarization.[105,203]

Determination of Lecithin/Sphingomyelin Ratio and Saturated Phosphatidylcholine[315]

The major surface-active component of the lung surfactant is DSPC, which represents 85% of the total lecithins. Its concentration in amniotic fluid tends to rise with increasing gestational age. The majority of the DSPC in amniotic fluid comes from the fetal lungs via tracheal effluent. The concentration of DSPC in amniotic fluid can be measured directly and correlated with FLM, or its concentration can be related to another lipid, sphingomyelin, and that ratio used to predict lung maturity. Although sphingomyelin is a minor component of pulmonary surfactant, it is ubiquitously distributed in cell membranes, especially those of erythrocytes, and is also found in plasma. Nearly all of the sphingomyelin in amniotic fluid is derived from non-lung sources; thus it has no role in the surfactant system in the lungs. The concentration of lecithin relative to sphingomyelin, the L/S ratio, tends to rise with increasing gestational age. This is not a uniform gradual increase; a rather sudden increase occurs at 34 to 36 weeks of gestation and correlates with the development of fetal lung maturity.[139]

Although the majority of laboratories use a commercially available method for L/S determination (Fetal-Tek, Helena Laboratories, Beaumont, Tex.), some continue to use methods developed in their own laboratories (the so-called "home brew" methods). Because there are many techniques, laboratories should be very careful when establishing medical decision limits. Some methods measure all phosphatidylcholine species, both saturated and unsaturated. Different staining methods will differentially stain phosphatidylcholine compared with the biological internal standard, sphingomyelin. The CAP proficiency testing program for FLM tests has shown a steady decline in the number of laboratories performing this test, from 234 in 1994 to 97 in 2004 (see Table 54-6).

Methodological details of both L/S ratio and DSPC procedures are given on the Evolve site that accompanies this book. The procedures described there should not be considered definitive or representative.[53,301,315]

Interpretation

The original maturity decision limit for the L/S ratio was 2.0 or greater.[319,320] Most laboratories use a method that omits the acetone precipitation step, which will produce slightly higher values. A conservative reference interval for lung maturity is an L/S ratio of 2.5 or greater. About 1% of babies delivered within 24 hours of obtaining an L/S ratio of greater than 2.5 can be expected to develop RDS; thus 99% of babies predicted to be mature will in fact be mature. Almost half of the infants with L/S ratios between 1.5 and 2.5, however, will not develop RDS. Thus in contrast to the high degree of reliability of a prediction of maturity, only one third of the babies predicted to be immature will in fact develop RDS.

Before the use of tight glycemic control during pregnancy, babies of diabetic mothers more frequently developed RDS.[273] A number of investigators have reported that infants of diabetic mothers more frequently develop RDS despite mature L/S ratios,[85] but other studies have reported no delay in lung maturity for infants of diabetic mothers.[133,306] In poorly controlled diabetic cases, both maturation delay[262] and lack of delay[223] have been reported. Although no RDS outcome studies exist, other studies of well-controlled diabetic mothers report no effect in the relationship between L/S ratio and gestational age.[223,36] For this reason, separate reference intervals are not recommended for well-controlled diabetic pregnancies.[20]

For multifetal pregnancies, separate specimens should be analyzed for each fetus. Infrequently, more than one fetus shares an amniotic fluid cavity. In such a case, a mature result is less predictive of maturity, because it represents a mixture of pulmonary surfactant from multiple fetuses. In the case of twins, the smaller is more likely to develop RDS than the larger.[225]

Serum has a large concentration of lecithin and sphingomyelin. The serum ratio varies between 1.5 and 2.0, depending on the individual. The values of blood-contaminated specimens therefore tend to be drawn into that range from either higher or lower values. A high L/S ratio in the presence of even substantial blood contamination can safely be interpreted as reflecting mature lungs.[135] Similarly, contaminated samples with very low ratios clearly reflect immature lungs. Borderline values of bloody specimens cannot be interpreted, because they may represent either very immature values falsely elevated or mature values falsely depressed. Various effects of meconium contamination have been reported, including some evidence

that the L/S ratio may be changed in the absence of contamination that is visible to the eye.[325] The chromatograms of fluids heavily contaminated with meconium are not interpretable.

Vaginal contamination of specimens obtained from a pool of fluid that has been present in the vagina for a relatively brief period does not affect either test.[109,258]

L/S ratio results show considerable differences among laboratories. For proficiency testing samples LM-09 and LM-10 from the CAP, the reported CVs were 26% (at mean L/S = 4.46) and 27% (at 2.31), respectively.[79]

Phosphatidylglycerol

The determination of PG is a commonly used qualitative method used to assess FLM in the United States. Measurement of PG was classically performed by thin-layer chromatography. It could be performed alone or in combination with other amniotic fluid phospholipids. The later test was known as a *lung profile* since its introduction in the early 1970s.[22] Although thin-layer chromatography is still offered by some reference and hospital laboratories, most hospital laboratories use a rapid slide method for qualitative PG detection. Several enzyme-based tests for quantitative PG have also been published, but none is widely used.[18,131,174,227]

The exact role of PG in lung surfactant is unclear.[55] Many claim that the appearance of PG in the amniotic fluid indicates the final biochemical maturation of surfactant,[156,191] but PG can be found in measurable quantities in amniotic fluid as early as 32 weeks,[129] and its presence in small quantities does not necessarily imply that the fetal lungs are mature.[95,129,221] The concentration of PG in amniotic fluid increases with gestational age. Most thin-layer chromatography techniques are positive when PG exceeds about 2 μmol/L. At this cutoff, results indicating maturity are almost always correct, but results indicating immaturity are frequently wrong.

AmnioStat-FLM

Most laboratories that offer PG testing use a qualitative rapid agglutination test (AmnioStat-FLM, Irvine Scientific, Santa Ana, Calif.) that uses less than 0.5 mL of amniotic fluid.[115,134,281] The protocol is as follows: 25 μL of amniotic fluid is mixed with 25 μL of a lecithin-cholesterol ethanol solution; 250 μL of phosphate buffer is added and mixed; 10 μL of this mixture is placed on a glass slide and mixed with 25 μL of an anti-PG reagent. Agglutination occurs in the presence of PG and is compared with three controls. Results are reported as negative, low-positive (0.5 to 2 μg/mL [0.5 to 2 mg/L]), or high-positive (2 μg/mL [2 mg/L] or greater). RDS rarely develops in an infant from a mother with a high-positive PG determined by AmnioStat. Although Irvine Scientific was unable to provide AmnioStat reagents to laboratories for much of 2004, it recently resumed production.

Interpretation

Several clinical outcome studies using AmnioStat have been reported.* Although positive PG results are about 99% predictive of maturity, negative results are highly unpredictive (RDS develops in about 25% of cases with a negative PG, depending on the population) and are therefore not useful clinically. A positive PG result is very useful in low-risk pregnancies that require cesarean section. Determination of PG is also useful for specimens contaminated with blood or meconium. PG is not found in either blood or meconium, and therefore results are not affected by the presence of either of these contaminants.[33,121]

Many clinicians rely on PG whenever they need to assess FLM in a diabetic patient.[113,318] No modern studies support this practice. In normal pregnancies, PG is detected by thin-layer chromatography (TLC) or AmnioStat-FLM at approximately 35 weeks' gestation. In diabetic patients, regardless of glycemic control, PG is detected about 1.5 weeks later.[96,223,320] Many diabetic patients will deliver term infants unaffected by RDS before any PG is detected.[262] The diabetic status of the patient does not affect the method of detection.[281]

Determination of the Lung Profile[191,192]

This method for assessing FLM was invented by Marie Kulovich and Louis Gluck in the early 1970s. Although it is still offered by some reference laboratories, most hospital laboratories have substituted newer techniques. The details of the procedure are available on the Evolve site that accompanies this book. The pattern of L/S ratio, phosphatidylinositol (PI), and PG are used to determine the status of fetal pulmonary maturation.

Foam Stability Index[292]

Many laboratories used a commercial version of this test, called Lumadex, FSI Fetal Lung Maturity Test (Beckman Instruments, Fullerton, Calif.), which was introduced in 1982.[205,291] Beckman Instruments discontinued this test in 1997. The procedure is described on the Evolve site that accompanies this book.

When pulmonary surfactant is present in amniotic fluid in sufficient concentrations, the fluid is able to form a highly stable surface film that can support bubbles. Other substances in the fluid, including proteins, bile salts, and salts of free fatty acids, are also capable of forming stable bubbles, but they can be removed from the film by ethanol, which competes with the other substrates for a position in the surface film.[71] The test makes use of the principle that more surfactant activity is necessary to support a stable foam as the fraction of ethanol in the mixture is increased.[291-294] Therefore a fixed volume of undiluted amniotic fluid is mixed with increasing volumes of ethanol, and the largest fraction of ethanol in which the amniotic fluid is still capable

*References 121, 128, 134, 158, 208, 317, 343.

of supporting a foam is determined. The highest fraction of ethanol at which a positive reading is obtained is the FSI.

Interpretation

An FSI value of 0.47 or greater is interpreted as mature. In two studies, a combined total of 270 fetuses with an FSI of 0.47 or greater was reported, two of which developed RDS. In 110 fetuses with an FSI of 0.46 or less, 44 (40%) developed RDS. Thus the test appears to have more false predictions of immaturity than the L/S ratio or surfactant/albumin ratio. Tubes and stoppers must be clean and free of detergents to prevent false-positive readings. The final concentration of the ethanol is critical. Ethanol is hygroscopic; therefore careful attention must be paid to its preparation and storage. The test should be conducted at 20 °C to 25 °C.[181] Specimens contaminated with either blood or meconium tend to give a falsely mature result.

Lamellar Body Counts[25]

Lamellar bodies avidly scatter light, producing a haziness in mature amniotic fluid.[111] These particles can be counted directly using the platelet channel of most whole blood cell counters. This technique is termed lamellar body count (LBC).[23,112] LBC is a direct reflection of surfactant concentration in amniotic fluid, in contrast to L/S ratio and TDx FLM II, which are ratios. Fetal urination lowers LBC, but does not affect results of the other two methods.

Lamellar bodies have a broad size distribution, ranging from 0.2 to 10 fL.[25] The whole blood cell counters used during the development of the LBC method used a size gate from 2 to 20 fL. Therefore only a portion of lamellar bodies are counted in these instruments.

Centrifugation of amniotic fluid can be omitted.[20,113] Mixing is critical—two minutes is recommended on a tube rocker or at least 20 inversions immediately before analysis.[230] Typical LBC results are from 0 to 150,000/μL. A detailed procedure is available on the Evolve site that accompanies this book.

Because of different platelet identification algorithms, counts will be lower or higher on different instruments. Instruments that use similar algorithms (for example, the resistive pulse instruments, Coulter Gen-S, Cell-dyn 3500, and Sysmex XE-2100) have high correlation but poor agreement.[305] The proportional bias was from −32% to +76% among these instruments. The Advia 120, a flow cytometer that uses a different platelet algorithm, did not correlate with the resistive pulse counters, but has been shown to predict FLM using a modified algorithm.[70] The imprecision (CV) is typically 6% to 8% at an LBC of 35,000/μL.[143]

Specimens containing mucus produce erratic results.[230] More than 1% contamination with blood initially increases LBC because of the addition of platelets, but lamellar bodies are trapped in any clots that occur thus lowering the LBC by up to 20%.[230] Moderate meconium contamination (A_{390} up to 0.5) increases LBC by 5000/μL or less.[112]

Interpretation

The maturity decision cutoff varies from 19,000 to 60,000/μL. Typically 35,000/μL is used,[230] but this is affected strongly by the instrument used. All clinical outcomes studies* have reported that LBC has high sensitivity (95% to 100%) but low specificity (about 70%) for prediction of RDS. A recent meta-analysis[346] reported that at a fixed sensitivity of 95%, the LBC specificity was 80%, whereas the L/S ratio specificity was 70%.

No studies of diagnostic accuracy exist for diabetic mothers. An assay comparison study of LBC, L/S ratio, and PG reported good agreement among the tests for 90 diabetic subjects with no cases of RDS.[107]

CHAPTER 55

Inborn Errors of Amino Acid, Organic Acid, and Fatty Acid Metabolism*

Piero Rinaldo, M.D., Ph.D.,
Sihoun Hahn, M.D., Ph.D.,
and Dietrich Matern, M.D.

With increasing frequency, inborn errors of metabolism (IEM) are recognized to be the underlying cause of clinical manifestations that are encountered in all venues of medicine from the fetus to the geriatric patient.[39,52,122] To adequately support the care of these patients, a new discipline has gradually developed, one that differs from a conventional clinical chemistry laboratory in the extent of interpretation that is necessary to make its results meaningful to the clinician. In the United States, this field is called *clinical biochemical genetics,* and is defined by the American College of Medical Genetics as the laboratory discipline that covers the biochemical diagnosis of IEM by metabolite and enzymatic analysis of physiological fluids and tissue and is concerned with (1) the evaluation and diagnosis of patients and families with inherited metabolic disease; (2) monitoring of treatment; and (3) distinguishing heterozygous carriers from noncarriers.[125]

Until recently, the practice of biochemical genetics was confined to a few academic centers in which services were driven by specific research interests. Although these laboratories made seminal contributions to our understanding of IEM and provided diagnostic services that were otherwise not available, in most cases they had limited capacity and slow turnaround time.[110] These and other factors contributed to a progressive decline of interest, research funding, and enrollment of young physicians and scientists in accredited training programs[136] to the point that biochemical genetics was deemed obsolete in anticipation of the predominance that nucleic acid–based diagnostics was forecast to have after the completion of the Human Genome Project. To date, however, the appreciation that irreplaceable information is derived by the biochemical analysis of proteins and small molecules has sparked a renewed interest in this discipline both at the clinical and research levels, a rebound also driven by the introduction of tandem mass spectrometry (MS/MS; see Chapter 7) into newborn screening programs (Figure 55-1) and the consequent surge of laboratory services needed for confirmatory testing and follow-up purposes.[24,27,78,140,145]

BIOCHEMICAL DIAGNOSIS

Although the diagnosis of a specific IEM is with a few exceptions strictly a laboratory process, two basic patterns of acute clinical presentation, called "intoxication" and "energy deficiency," are informative clinical elements that should not be overlooked in the anticipation of a laboratory diagnosis.[118] A clinical picture of the intoxication type is found when a newborn or infant experiences a trigger event and rapidly becomes comatose after a symptom-free period. Alternatively the absence of a symptom-free period is more indicative of an energy deficiency type of neurological distress. In both cases, the failure to respond to symptomatic therapy and a rapid deterioration of the patient's general status are typical manifestations. Organic acidemias, urea cycle disor-

*The authors gratefully acknowledge the contributions by Robert H. Christenson and Hassan M. E. Azzazy on which portions of this chapter are based.

ders, and a few other disorders of amino acid metabolism are classic examples of endogenous intoxication. Fatty acid oxidation (FAO) disorders may present with a combination of intoxication and energy deficiency manifestations.[111]

Once a clinical suspicion has been raised, a basic set of routine laboratory tests (blood electrolytes and gases, glucose, ammonia, lactate, and urine ketones) is strongly recommended as the first level of laboratory evaluation. General guidelines for diagnostic orientation on the basis of the outcome of these tests are shown in Table 55-1 and discussed in greater detail elsewhere.[108,118] Recognition of informative patterns, for example hypoglycemia without ketonuria in medium-chain acyl-CoA dehydrogenase (MCAD) and other FAO disorders, could implementation of appropriate therapeu independently of the turnaround time of speci tory investigations. Obviously, deviations fro patterns (such as ketonuria in MCAD defici unexpected combinations[143] should not be considering the unpredictable role that genetic, environmental factors may play in individual ca

In addition to the traditional role of investiga tomatic patients, biochemical genetics is evolving cipline with a major focus on early diagnosis and of morbidity and mortality.[112] Prenatal diagnosis ticularly newborn screening are obvious exampl trend; postmortem screening enables genetic couns testing of at-risk relatives, thereby preventing morb mortality in other affected but still undiagnosed, or family members.[9] Hopefully the need to provide a m autopsy in the future will decline in parallel to the ex of newborn screening programs.[102]

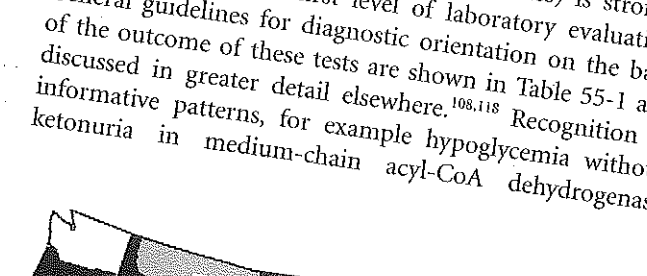

Figure 55-1 Current status of newborn screening in the United States for disorders of amino acid, organic acid, and fatty acid metabolism by tandem mass spectrometry. **A** *(black):* active program, screening required by the state or ongoing universal pilot. **B** *(dark grey):* program not mandated, testing of selected populations or limited pilot programs. **C** *(light grey):* testing mandated but not implemented. **D** *(white):* no MS/MS screening. Georgia, Michigan, New York, and Virginia screen for only one disorder by MS/MS, Connecticut and Maryland for two. *(Data obtained from National Newborn Screening & Genetic Resource Center web site [http://genes-r-us.uthscsa.edu/resources/newborn/screenstatus.htm, updated Nov 11, 2003].)*

Prenatal Diagnosis

Despite constant progress in medical treatment, mos result in severe morbidity and inevitable mortality in life. As these disorders typically follow an autosomal sive mode of inheritance, the recurrence risk in subseq pregnancies is 25%. Genetic counseling of parents con of a balanced assessment of (1) familial risk factors (pare consanguinity and ethnic origin), (2) risk of pregnancy as a consequence of the sampling procedure (0.5% to 1% chorionic villus sampling [CVS], 0.5% by amniocentes (3) risk of maternal complications,[114] and (4) the potent fallacy of "experimental" procedures yielding uninformati results because of limited prior experience.[112]

Methods used for prenatal diagnosis of IEM have differ ent requirements in terms of timing, sample collection, and options for independent confirmation. CVS is performed at 10 to 12 weeks of gestational age, has a higher risk of fetal loss, and entails the occurrence of artifactual results caused by contamination with maternal tissue, which has made this

TABLE 55-1 Typical Outcome of Routine Laboratory Investigations in Disorders of Amino Acid, Fatty Acid, and Organic Acid Metabolism

approach very unreliable in specific disorders (e.g., methylmalonic acidemia). Amniocentesis is performed later in pregnancy (16 to 19 weeks) and provides both amniocytes and amniotic fluid to be used for independent and complementary diagnostic methods. Reliance on separate tests based on independent methods performed by laboratories with adequate prior experience is strongly encouraged to avoid the occurrence of either incorrect or inconclusive results. For example, Figure 55-2 shows the results obtained by analysis of an amniotic fluid specimen from a pregnancy at risk for methylmalonic acidemia (*cblC* complementation group).[139] The finding of elevated concentrations of methylmalonic acid, propionylcarnitine, and homocysteine using different MS/MS methods provides strong biochemical evidence of an affected fetus. However, validation of these results by assay of [^{14}C]-propionate fixation and cobalamin uptake in cultured amniocytes remains an essential part of the recommended diagnostic process. When a multianalyte approach is not possible, at least two separate laboratories should perform the same test independently to minimize the risk of incorrect results.[8] The major advantages of direct metabolite analysis in amniotic fluid are the independence from tissue expression and a rapid turnaround time.

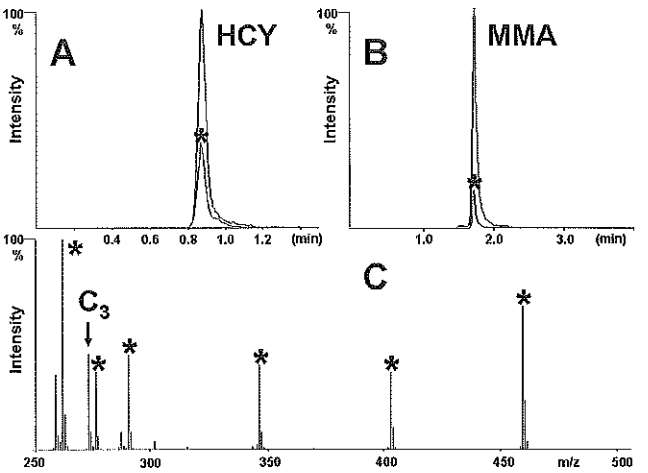

Figure 55-2 Multi-analyte approach to the prenatal diagnosis of methylmalonic acidemia (*cblC* complementation group) by metabolite analysis in cell-free supernatant of amniotic fluid collected at 16 weeks of gestational age. The symbol * marks internal standards. **A,** Determination of total homocysteine by LC-MS/MS (selected reaction monitoring, SRM, transition m/z 136 to m/z 90 and m/z 140 to m/z 94 for the d_4-labeled internal standard).[74] The concentration of total homocysteine was 15.7 µmol/L (0.7 to 2.0 µmol/L). **B,** Determination of methylmalonic acid by LC-MS/MS (SRM, transition m/z 231 to m/z 119 and m/z 234 to m/z 122 for the d_3-labeled internal standard).[73] The concentration of methylmalonic acid was 8.7 µmol/L, the reference interval for 16 to 19 weeks of gestational age is 0.2 to 0.7 µmol/L. **C,** Determination of propionylcarnitine by LC-MS/MS (parent of m/z 85 scan, the $[M+H]^+$ ion of C3 is m/z 274, m/z 277 for the internal standard). The concentration was 5.6 µmol/L (1.5 to 1.8 µmol/L), the C3/C4 ratio was 6.9 (0.9 to 2.6).

Newborn Screening

More than 4 million babies are born in the United States every year. Newborn screening has become an important and effective component of preventive medicine, allowing detection of treatable disorders before irreversible clinical symptoms manifest themselves. Originally instituted in the 1960s for the early detection of phenylketonuria (PKU), newborn screening programs have gradually added assays for other disorders over the years. There is, however, a striking level of discrepancy in the scope of programs offered by states even in the same region, a reality that seems to be driven more by political decisions than scientific evidence and expert opinions.[33] This situation has received even greater scrutiny since MS/MS has dramatically expanded the number of IEM detectable in neonatal blood spots, notably by performance of a single multiplex analysis of acylcarnitine and amino acid profiles.[24,78] The inclusion of these disorders as a whole in newborn screening panels has been controversial, because with few exceptions their incidence, natural history, prospective screening experience, and effectiveness of treatment have not been defined yet.[50] However, cautionary concerns often underestimate the complex differential diagnosis that is required for any abnormal metabolites detected in amino acid, organic acid, and acylcarnitine profiles.[24,101] Actively developing tools for proper confirmatory testing and differential diagnosis of all detectable IEM seems more reasonable than debating the exclusion of one or more rare conditions that are detected anyway, at no additional cost, and could be misinterpreted as "false positives" of a better known condition. Finally, because some inborn errors of amino acid, organic acid, and fatty acid metabolism are undetectable by MS/MS analysis of amino acids and acylcarnitines, a negative newborn screening outcome should not be regarded as a blanket exclusion of metabolic disorders in patients presenting with unexplained clinical manifestations at any age.

Evaluation of Symptomatic Patients

When a patient with acute metabolic decompensation is brought to medical attention, the utmost consideration should be given to the immediate collection of urine and blood samples. Specimens collected even after a partial recovery may not reveal diagnostic abnormalities otherwise detectable, or more easily detectable, under acute conditions. Any volume of urine (stored at −20 °C with no preservatives, or even a wet diaper brought to the emergency room) and plasma/serum (~0.5 mL, stored at −20 °C) are adequate to perform specialized tests. Quantitative profiling of amino acids, carnitine, acylcarnitines, and fatty acids in plasma, organic acids, and acylglycines in urine is the method of choice to reach a biochemical diagnosis of these disorders. Alternatively a blood spot on filter paper could provide enough material for one or more of the investigations

described in this chapter. In case of death, collection of body fluid and tissue should be secured according to available protocols.[22,115]

As already stated, the extent of interpretation that is necessary to make results meaningful to the clinician is the defining characteristic of biochemical genetics as a laboratory discipline. An interpretive report of complex organic acid, amino acid, and acylcarnitine metabolite profiles should include the following elements: (1) an overview of positive and negative results (e.g., ketotic versus nonketotic dicarboxylic aciduria, and presence or absence of alloisoleucine in specimens with elevated concentrations of branched-chain amino acids); (2) quantitative determination in comparison to age-matched reference values; (3) a list of possible diagnoses with correlation with available clinical information; (4) clinical and laboratory criteria of differential diagnosis; (5) recommendations for additional biochemical testing and in vitro confirmatory studies (enzyme assay and molecular analysis); (6) name and means to contact investigators able to provide such studies at times available only on a research basis; and (7) a phone number to reach the laboratory director who is familiar with the report in case the referring physician has additional questions.

Postmortem Screening

In view of the high mortality rate that is associated with acute episodes of metabolic decompensation, it is not surprising that sudden death has been sporadically associated with a few inborn errors of amino acid, organic acid, and energy metabolism, such as (1) fumaric acidemia, (2) methylmalonic acidemia, (3) glutaric acidemia type I, (4) biotinidase deficiency, (5) glycogenoses, and (6) disorders of the mitochondrial oxidative phosphorylation pathway. Despite these anecdotal reports, these disorders are unlikely to have a significant role among the metabolic causes of sudden death. Conversely, the number of cases affected with a FAO disorder who were recognized either postmortem or after the diagnosis of an affected sibling has soared in the last few years.[9,17] Based on these observations, experts postulate that FAO disorders might be responsible for up to 5% of children who die suddenly and unexpectedly from birth to 5 years of age, particularly with evidence of acute infection.[16]

Figure 55-3 shows a flow chart for the postmortem evaluation of sudden and unexpected death that is centered on the analysis of acylcarnitines in blood and bile spots.[111] Blood and bile could be conveniently collected on a single filter paper card, one identical to those used for newborn screening, which can be shipped at room temperature once properly dried. Both specimens should be collected to detect patients who may have only mild blood abnormalities when carnitine is depleted (Figure 55-4). In cases with a higher level of suspicion, an effort should be made to collect and freeze a specimen of liver[16] and a skin biopsy,[71] which could be analyzed only if needed to reduce cell culture workload.[44]

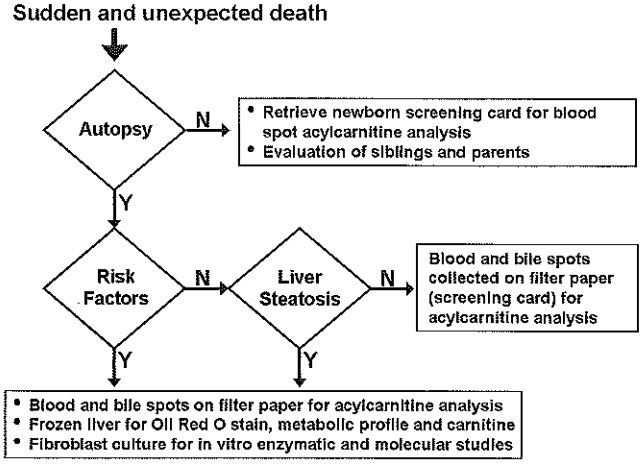

Figure 55-3 Protocol for the postmortem screening of FAO disorders. *(From Rinaldo P, Matern D, Bennett MJ. Fatty acid oxidation disorders. Ann Rev Physiol 2002;64:477-502.)*

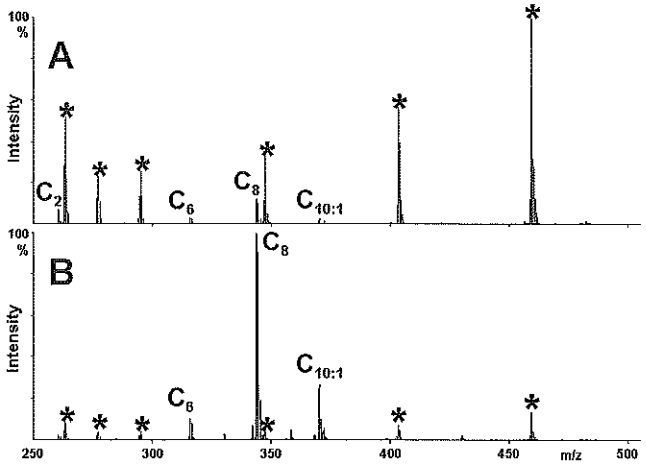

Figure 55-4 Postmortem diagnosis of MCAD deficiency by acylcarnitine analysis of blood and bile collected at autopsy. The patient was a 3-year-old, previously healthy child who had symptoms of a viral respiratory tract infection. He was a compound heterozygote for the common 985A>G mutation and another mutation. The symbol * marks the internal standards, same amount added to both specimens. **A,** Blood acylcarnitine profile. The concentrations of acetylcarnitine (C2), hexanoylcarnitine (C6), octanoylcarnitine (C8), and decenoylcarnitine (C10:1) were 2.8, 0.3, 1.4, and 0.3 μmol/L, respectively (for reference intervals see Table 55-8). **B,** Bile acylcarnitine profile (after 10× dilution). The concentrations of C2, C6, C8, and C10:1 were 52.8, 73.1, 665.6, and 181.3 μmol/L, respectively (for reference intervals see Table 55-8). The bile/blood C8 ratio was 475. In postmortem urine, hexanoylglycine was also markedly elevated (69.6 mmol/mol creatinine; reference interval 0.1 to 1.3).

BOX 55-1 Factors That Increase the Risk of an Underlying Metabolic Disorder in Cases of Sudden Unexpected Death

Family history of sudden infant death syndrome (SIDS) or other sudden, unexplained deaths at any age
Family history of Reye's syndrome
Maternal complications of pregnancy (acute fatty liver of pregnancy, HELLP syndrome, others)
Lethargy, vomiting, fasting in the 48 hours before death
Macroscopic findings at autopsy
  Fatty infiltration of the liver and/or other organs
  Dilated or hypertrophic cardiomyopathy
Allegation of child abuse (not trauma, physical harm)
Autopsy evidence of infection that routinely would not represent a life-threatening event

HELLP, Hemolysis, elevated liver enzymes, low platelets.

Although fatty infiltration of the liver and/or other organs (e.g., heart and kidneys) is a common observation in FAO disorders, the finding of macroscopic steatosis should not be used as the only criterion in deciding whether to investigate a possible underlying FAO disorder during the postmortem evaluation of a case of sudden death. Special attention should be paid to the risk factors listed in Box 55-1, and allegations of child abuse should also be fully investigated to avoid any recurrence of a tragic miscarriage of justice,[49] with the exception of obvious cases of trauma or physical harm. The frozen liver and skin biopsy could be discarded at a later time without further testing when a credible cause of death has been established, but could otherwise be crucial to reach a proper diagnosis and conclusive confirmation in vitro. If parental permission to perform an autopsy is not granted, an attempt should be made to retrieve leftover specimens that may still be available in a hospital setting. If death occurs at home, retrieval of any unused portion of the blood spots collected for newborn screening could be arranged via a written request submitted to the state laboratory, as long as the storage period, ranging from only a few weeks to indefinitely, had not expired already in the state where the patient was born.[95]

DISORDERS OF AMINO ACID METABOLISM

The concentrations of individual amino acids in physiological fluids reflect a balance between (1) intestinal uptake, (2) anabolic use by the liver, (3) the synthesis and turnover of the body's structural proteins, and (4) integrity of renal functions (filtration and tubular reabsorption). Any interference or unusual event in the metabolism, growth, or replication of the body's cells and tissues that affects protein and amino acid metabolism could be accompanied by either accumulation or excessive losses of one or more amino acids.[121]

Inborn errors of amino acid metabolism will manifest themselves at anytime in a person's life, but most become evident in infancy and early childhood. Affected patients may have failure to thrive, neurological symptoms, digestive problems, locomotor retardation, and a wide spectrum of laboratory findings. If not diagnosed promptly and treated properly, these disorders can result in poor growth, mental retardation, and death.[13]

Table 55-2 shows a summary of known disorders of amino acid metabolism and transport, including information about their incidence, major clinical features and biochemical patterns, availability of prenatal diagnosis and newborn screening, and association with sudden unexpected death. Several of these disorders are discussed next.

Classic Phenylketonuria and Other Hyperphenylalaninemias

Phenylalanine is an essential amino acid. Dietary intake in excess of anabolic needs is converted to tyrosine by phenylalanine hydroxylase and further degraded via a ketogenic pathway (Figure 55-5). A primary or cofactor-related defect of phenylalanine hydroxylase activity causes accumulation of phenylalanine, phenylketones, and phenylamines.[14,119] Several distinct forms of hyperphenylalaninemia exist (see Table 55-2); all are inherited as autosomal recessive traits. They have a collective prevalence of 1:10,000 to 1:20,000 live births, with classic PKU being the most common entity and GTP cyclohydrolase I the rarest one. Together with congenital hypothyroidism and galactosemia, hyperphenylalaninemias are the only IEMs that are screened for at birth in all of the United States and their territories.

Although vomiting may be an early symptom severe enough to be misdiagnosed as pyloric stenosis, patients with classic PKU are clinically silent at birth and neurological manifestations typically do not become evident until a few months of age. To avoid missing a PKU case, infants should not be screened until at least 24 hours after birth. Although a delayed diagnosis is an exceptionally rare event for properly screened newborns, the consequences are severe. PKU infants may lose about 50 points in their adult IQ if left untreated until the end of the first year of life. Those who are diagnosed even later require institutional care because of severe mental retardation and hyperactivity. Other common findings in untreated patients include fair skin and blue eyes, microcephaly, prominent maxilla with widely spaced teeth, enamel hypoplasia, and growth retardation. Some have a seborrheic or eczematous skin rash, which progressively attenuates with age. Although there are no consistent neurological findings, most infants are hypertonic with increased deep tendon reflexes. About one fourth of children have seizures, and more than 50% have abnormal electroencephalographic (EEG) findings.

The criteria for a biochemical diagnosis of untreated classic PKU are: (1) a plasma phenylalanine level above 20 mg/dL (1.2 mmol/L) (Figure 55-6, *A*); (2) a phenylalanine/tyrosine ratio >3; (3) increased urinary levels of metabolites of phenylalanine (i.e., phenylpyruvic and 2-hydroxyphenylacetic acids); and (4) a normal concentration of the cofactor

Attacks of stupor and asterixis	Lysine (U), orotic (U), mild elevation of GLN, ALA, CIT, others (B)	Linkage analysis	Not available	Reported after alcohol ingestion
Psychotic episodes	Hyperexcretion of ALA, SER, THR, VAL, LEU, ILE, PHE, TYR, TRP, HIS, GLN, ASN (U)	Not reported	Not available	/
/	Proline, hydroxyproline, glycine (U)	Not reported	Not available	/

tetrahydrobiopterin (BH_4). In vitro assay of enzyme catalytic activity and genotyping are not commonly applied in clinical practice, making the biochemical phenotype a de facto conclusive diagnosis immediately followed by dietary treatment. The goal of therapy is to sustain growth and keep serum phenylalanine concentrations below an appropriate-for-age threshold to minimize the occurrence of neurological damage.[106] Frequent monitoring is critical, because excessive restriction may lead to phenylalanine and tyrosine deficiency, the latter requiring exogenous supplementation.

Dietary treatment should be started as soon as possible and ideally before 2 weeks of age.[103] Although a less strict dietary regimen is possible after 6 years of age, some forms of restriction are necessary indefinitely because central nervous system (CNS) damage has been described after discontinuation of treatment beyond childhood.[6] Pregnant women with PKU who are not on a low phenylalanine diet and have phenylalanine levels >360 μmol/L (6 mg/dL) have higher risks of either spontaneous abortion or the birth of offspring with microcephaly, congenital heart defects, facial dysmorphism, and developmental delay caused by the teratogenic effect of phenylalanine.[63,69]

In about 2% of cases, hyperphenylalaninemia is due to a deficiency of either biosynthesis or recycling of BH_4, the cofactor of phenylalanine hydroxylase and related enzymes (see Figure 55-5).[62] These infants could be diagnosed with PKU at first, but they deteriorate neurologically despite adequate dietary control. BH_4 is a cofactor for phenylalanine, tyrosine, and tryptophan hydroxylases. The latter two enzymes are involved in the synthesis of the neurotransmitters dopamine and serotonin. BH_4 is also a cofactor for nitric oxide synthase, which catalyzes the generation of nitric oxide from arginine. All patients with hyperphenylalaninemia should be routinely tested to rule out the possibility of a cofactor deficiency.[96]

Four enzyme deficiencies leading to BH_4 deficiency have been reported (see Table 55-2). 6-Pyruvoyltetrahydropterin synthase (6-PTS) is found in approximately 50% of all cases. They are clinically indistinguishable from classic PKU when detected by newborn screening, but progressively deteriorate with loss of head control, hypertonia, drooling, swallowing difficulties, and myoclonic seizures around 3 months of age. Plasma phenylalanine levels could be as high as those in classic PKU or in the range of benign hyperphenylalaninemia (<1.0 mmol/L). Measurement of urinary neopterin and biopterin provides a tool for the differential diagnosis among these disorders.[14]

Infants with benign hyperphenylalaninemia are occasionally identified because of a moderately elevated blood concentration of phenylalanine. These patients have a partial deficiency of phenylalanine hydroxylase with residual enzyme activity up to 35% of normal subjects. Although detected by neonatal screening, they remain healthy without dietary treatment once the possibility of an underlying cofactor deficiency has been ruled out.

Tyrosinemia Type 1

Tyrosine derives from the breakdown of dietary or tissue proteins or through the hydroxylation of the essential amino acid phenylalanine. Hepatorenal tyrosinemia (tyrosinemia type I, TYR-I) is an autosomal recessive disease caused by a deficiency of the enzyme fumarylacetoacetase (Figure 55-7),

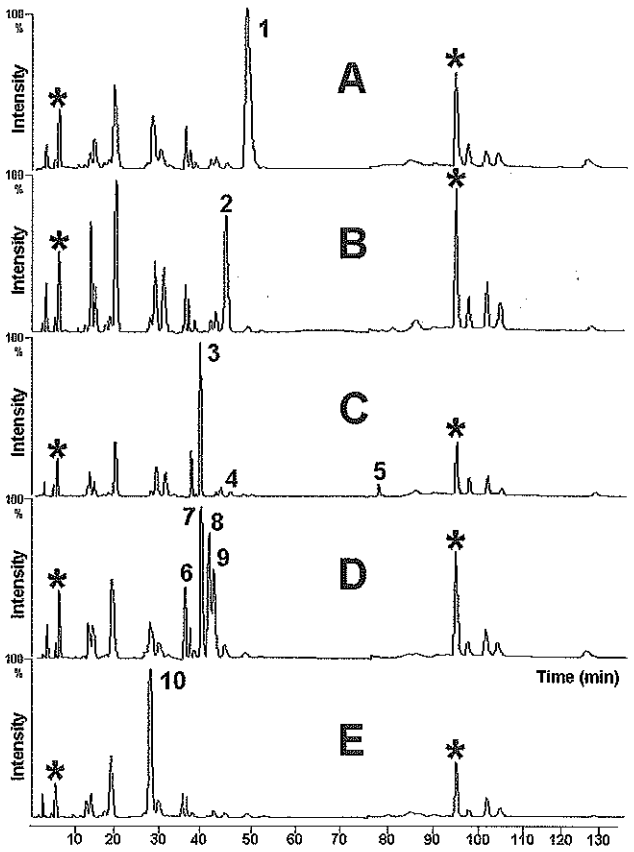

Figure 55-6 Plasma amino acid profiles by ion-exchange chromatography. **A,** Phenylketonuria (16 day old), phenylalanine 1550 μmol/L. **B,** Tyrosinemia type I (10 day old), tyrosine 696 μmol/L. **C,** Homocystinuria (8 year old), methionine 885 μmol/L, free homocysteine 38 μmol/L. **D,** Maple syrup urine disease (6 month old), valine 194 μmol/L, allo-isoleucine 693 μmol/L, isoleucine 636 μmol/L, leucine 418 μmol/L. **E,** Nonketotic hyperglycinemia (3 days old), glycine 1624 μmol/L. For age-matched reference intervals see Shapira et al.[12] **Peak legend:** *1,* Phenylalanine; *2,* tyrosine; *3,* methionine; *4,* mixed disulfide; *5,* free homocysteine; *6,* valine; *7,* allo-isoleucine; *8,* isoleucine; *9,* leucine, *10,* glycine. The symbol * marks the internal standards glucosaminic acid (retention time 6 minutes) and aminoethylcysteine (retention time 97 minutes), signal abundance is normalized on the intensity of the latter.

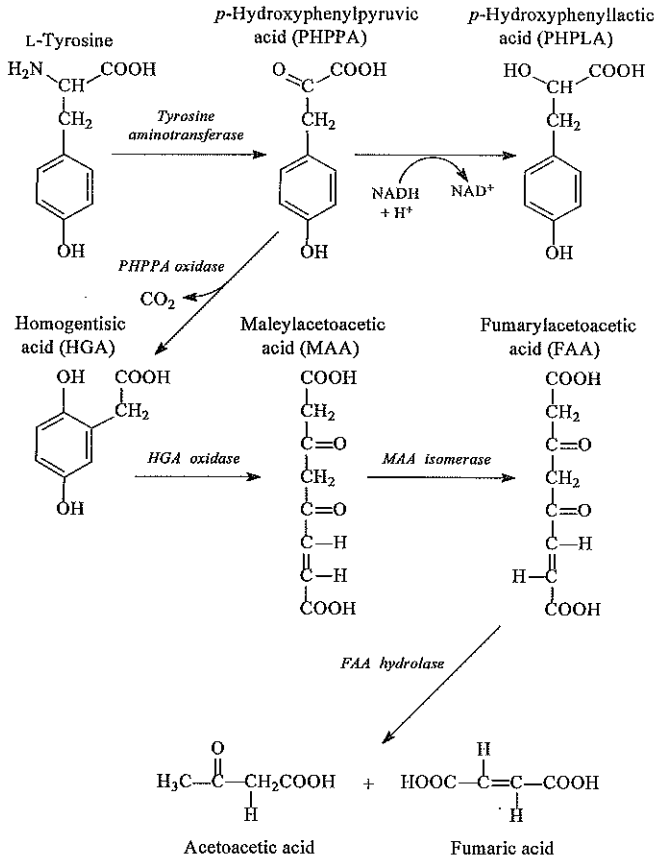

Figure 55-7 Metabolic pathway of tyrosine.

which is expressed primarily in the liver and renal proximal tubule.[90] The incidence of TYR-I is approximately 1 in 100,000, with well known clustering of cases in Scandinavia and the Lac-St. Jean region of Quebec (Canada). In the United States, screening for TYR-I is not offered in 35 states, with a cumulative number of births corresponding to 76% of all babies born each year (see Table 55-2). Under these circumstances, a clinical encounter with an undiagnosed and acutely ill patient is a realistic possibility in most pediatric gastroenterology practices. Symptoms are highly variable and include (1) acute liver failure, (2) cirrhosis, (3) hepatocellular carcinoma, (4) renal Fanconi syndrome, (5) glomerulosclerosis, and (6) crises of peripheral neuropathy that mimic acute intermittent porphyria caused by an accumulation of 5-aminolevulinic acid.[89]

An elevated concentration of tyrosine in plasma (Figure 55-6, *B*) is an expected finding of TYR-I but lacks specificity. A biochemical diagnosis is based instead on the detection in urine of succinylacetone (4,6-dioxaneheptanoic acid), the by-product of fumarylacetoacetic acid, which is the intermediate immediately upstream of the enzyme defect.[58] Absence of this metabolite in a patient with elevated plasma tyrosine and a urinary pattern of tyrosyluria (elevated excretions of 4-hydroxy phenyllactic acid, 4-hydroxy phenylpyruvic acid, and N-acetyltyrosine) points to any of several alternative causes, including other inherited disorders (tyrosinemia type II and type III, hypertyrosinemia of the premature, gluconeogenesis disorders, galactosemia, fructosemia, peroxisomal disorders) and acquired conditions (hepatitis, dietary load of aromatic amino acids, and overgrowth of intestinal flora). However, there have been rare instances when a patient with a diagnosis of TYR-I confirmed by DNA analysis does not excrete succinylacetone (Figure 55-8), suggesting that genotyping should still be pursued in patients with strongly suggestive clinical manifestations but no accumulation of succinylacetone.

NTBC (2-(2-nitro-4-trifluoro-methylbenzoyl)-1,3-cyclohexanedione) is a chemical initially developed as a herbicide. Animal studies show that NTBC is an inhibitor of

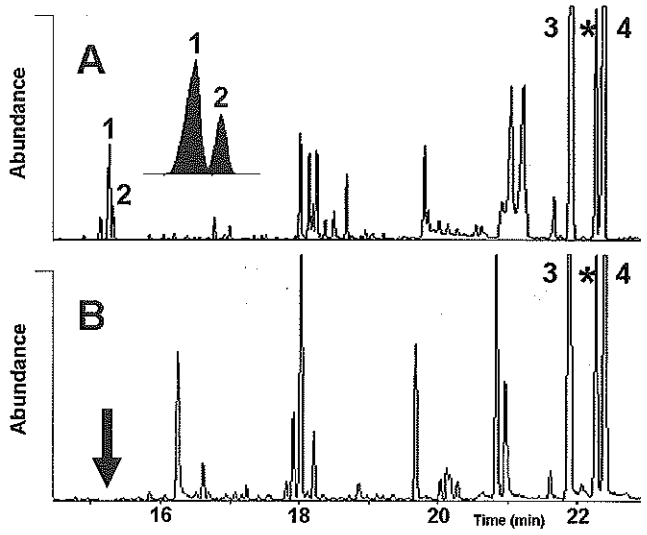

Figure 55-8 Partial urine organic acid profiles (15-23 minute portion of a 33 minute run) of two patients with tyrosinemia type I. **A,** Acutely ill patient with markedly elevated excretion of succinylacetone, pre-NTBC treatment. The insert shows the selected ion chromatogram of the $[M-15]^+$ ion of succinylacetone O-TMS-oxime TMS ester, m/z 212; **B,** Fifteen month old patient, succinylacetone was not detected by either total ion current (*arrow*) or selected ion chromatogram in three different urine specimens. This patient was later shown to be compound heterozygote for the French Canadian common splice mutation (IVS12+5G>A) and another previously unreported mutation. **Peak legend:** *1,* Succinylacetone (oxime, peak I); *2,* succinylacetone (oxime, peak II); *3,* 4-hydroxy phenyllactic acid; *4,* 4-hydroxy phenylpyruvic acid (oxime). The symbol * marks the internal standard (pentadecanoic acid), signal abundance is normalized to the intensity of the internal standard peak.

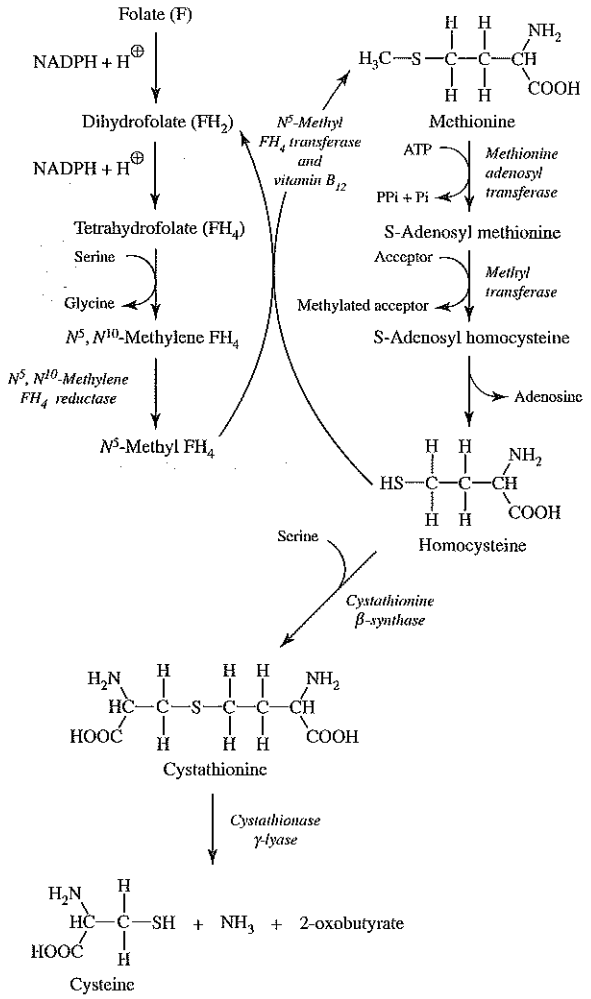

Figure 55-9 Biochemical pathways of the conversion of methionine to homocysteine and cysteine.

4-hydroxyphenylpyruvate dioxygenase, an enzyme of the tyrosine pathway located upstream of fumarylacetoacetate hydrolase. Pharmacological doses of NTBC virtually prevent the synthesis of succinylacetone and have become the treatment of choice for TYR-I in combination with dietary restriction and liver transplantation.[70]

Homocystinuria

Methionine, homocysteine, and cysteine are linked by the methylation cycle and transsulfuration pathway (Figure 55-9).[91] Conversion of methionine into homocysteine proceeds via the formation of S-adenosyl intermediates including S-adenosylmethionine, the methyl group donor in a wide range of transmethylation reactions. Homocysteine is further condensed with serine by cystathionine β-synthase to form cystathionine.

A defect of cystathionine β-synthase is an autosomal recessive disorder with an incidence of approximately 1:350,000 live births. In the United States, screening for homocystinuria is not offered in 23 states, corresponding to 53% of all babies born each year (see Table 55-2). Clinical manifestations are nonspecific at first and may include failure to thrive and developmental delay. A diagnosis is usually delayed 3 years or more if newborn screening is not available.[92] Ophthalmological problems include downward dislocation of the lens, myopia, and glaucoma; retinal detachment and degeneration, and optic atrophy and zonal cataracts may develop later in life. Osteoporosis is common after childhood when patients, as in Marfan syndrome, tend to be tall, with thinning and elongation of long bones near puberty. Besides mental retardation found in more than half of patients, neurological manifestations include seizures, abnormal EEG, and psychiatric disturbances. Thromboembolic episodes are common and involve both large and small vessels, especially in the brain, and constitute the major cause of morbidity and mortality. Thrombosis of carotid or renal arteries is a frequent cause of death.

The biochemical phenotype of homocystinuria is characterized by increased plasma concentrations of methionine, free homocysteine and cysteine-homocysteine disulfide, together with low cystine (Figure 55-6, *C*).[40] Determination of total homocysteine after treatment of the sample with

reducing agents is useful because 80% of homocysteinyl moieties are bound to protein. The differential diagnosis of hyperhomocysteinemia includes (1) remethylation defects, (2) 5,10-methylene-tetrahydrofolate reductase deficiency, (3) 5-methyl-tetrahydrofolate-homocysteine-methyltransferase deficiency, and (4) defects of cytosolic cobalamin metabolism. There are at least six distinct defects in cobalamin metabolism, designated as *cblC, cblD, cblE, cblF, cblG,* and *cblH.*[139] Patients with *cblC, cblD,* and *cblF* defects have methylmalonic aciduria in addition to homocystinuria, because formation of both adenosylcobalamin and methylcobalamin is impaired.

The methylenetetrahydrofolate reductase enzyme reduces 5,10-methylenetetrahydrofolate to form 5-methyltetrahydrofolate, which provides methyl groups necessary for homocysteine remethylation to methionine. The severity of the enzyme defect and of clinical symptoms varies considerably. Completely absent enzyme activity results in neonatal apneic episodes, myoclonus leading to coma, and death, whereas partial deficiency may result in mental retardation and seizures. Premature cardiovascular disease or peripheral neuropathy could be the only manifestation. A common polymorphism (677C>T) is associated with enzyme thermal lability and mild elevation of homocysteine in the presence of folate insufficiency, implicating a risk for both vascular disease[61] and neural tube defects.[88]

Maple Syrup Urine Disease

Leucine, isoleucine, and valine are the three essential branched-chain amino acids. They undergo decarboxylation by branched-chain α-ketoacid dehydrogenase, a complex enzyme that requires thiamine pyrophosphate as a coenzyme (see Chapter 30).[29] This complex is composed of four subunits, $E_1\alpha$, $E_1\beta$, E_2, and E_3. The E_3 subunit is shared by two other dehydrogenases, pyruvate dehydrogenase and α-ketoglutarate dehydrogenase. A defect on any component of the complex causes maple syrup urine disease (MSUD), an autosomal recessive disorder with an incidence of approximately 1:250,000 live births. In the United States, screening for MSUD is not offered in 21 states, corresponding to 46% of all babies born per year. About 75% of affected patients suffer from a severe classical form and the remainder from intermediate or intermittent forms.

Babies with classical MSUD present with poor feeding and vomiting during the first week of life followed by lethargy and coma within a few days. Hypertonia, rigidity, and severe opisthotonus are often interpreted as signs of general sepsis and CNS infection. Seizure and hypoglycemia are also common. At a more advanced stage, neurovegetative dysregulation with respiratory distress, bradycardia, and hypothermia may appear. Routine laboratory work is only remarkable for severe metabolic acidosis, and death rapidly ensues in untreated patients.

In some patients, symptoms appear after a symptom-free period of 1 year or more, occasionally in adolescence or even adulthood. Vomiting, ataxia, lethargy, and even coma characterize intermittent episodes of acute decompensation. Once they recover, patients return to a normal status with no obvious sequelae. Such episodes are triggered by catabolic stress, infections, or increased protein intake, and are associated with laboratory findings that are indistinguishable from neonatal-onset MSUD. Finally a chronic, progressive form of MSUD has also been described with (1) persistent anorexia, (2) chronic vomiting, (3) failure to thrive, (4) hypotonia, and (5) osteoporosis. Most patients remain undiagnosed until the occurrence of an acute neurological crisis.

A diagnosis of MSUD is suspected when a patient's urine, sweat, and particularly ear wax have the characteristic odor of maple syrup. At the bedside, mixing urine with a solution of 2,4-dinitrophenylhydrazine (DNPH) is a simple and rapid test to confirm a clinical suspicion,[12] a practical alternative to quantitative amino acid analysis if the latter is not available on site. Eventually, plasma amino acid analysis must be performed to show marked elevation of leucine (usually the prominent amino acid), isoleucine, and valine plus the pathognomonic presence of L-alloisoleucine (Figure 55-6, *D*). L-Alloisoleucine is a stereoisomer derived through stepwise racemization and keto-enol tautomerization of (2*S*) 2-keto-3-methylvaleric acid to its (2*R*) enantiomer, followed by transamination.[83] The 2-keto acids, the substrates immediately upstream of the enzyme block, are responsible for the positive DNPH test, and their respective hydroxy analogues are detectable by urine organic acid analysis after stabilization of the 2-keto groups via oximation. An elevated excretion of 2-hydroxyisovaleric acid could be the most informative finding in asymptomatic patients with intermediate and intermittent MSUD.

Cornerstones of treatment are dietary restriction of branched-chain amino acids and high dose thiamine, the latter showing responsiveness in cases with mild and/or intermittent presentations. Acute episodes are life threatening and require aggressive treatment; peritoneal dialysis may be necessary because renal clearance of the toxic metabolites is poor.[59]

Urea Cycle Defects

Enzymes of the urea cycle regulate the disposal of the amino groups removed by transamination and deamination of amino acids before their carbon skeleton is metabolized to gluconeogenic (most amino acids) or ketogenic precursors (leucine and lysine), or both (isoleucine, phenylalanine, tyrosine, and tryptophan). Disorders described in this pathway include (1) carbamylphosphate synthase (CPS) deficiency, (2) X-linked ornithine transcarbamylase (OTC) deficiency, (3) argininosuccinate synthase (ASS) deficiency (citrullinemia), (4) argininosuccinate lyase (AL) deficiency, and (5) arginase deficiency (argininemia).[18] The inclusion of these disorders in newborn screening programs varies from 2 to 20 U.S. states (5% to 32% of births) and is summarized in Table 55-2 (see also Figure 24-2, p. 802).

Patients with urea cycle defects may present at any age. In the neonatal period, a variable but usually brief interval is

followed by the clinical manifestations of hyperammonemia: poor feeding, vomiting, lethargy or irritability, coma and not infrequently death when cases are not properly diagnosed and aggressively treated. In infancy, the symptoms are similar to the neonatal period, but less severe and more variable. Neurological abnormalities also include ataxia and irritability. These patients are often misdiagnosed as having gastrointestinal disorders, food allergies, behavioral problems, or nonspecific hepatitis. In children and adults, chronic neurological problems are characterized by (1) learning difficulties, (2) mental retardation, (3) behavioral problems, and (4) cyclic vomiting, which occasionally deteriorates to acute decompensation with severe encephalopathy.[93] Arginase deficiency differs by the frequent absence of hyperammonemia and a clinical picture of spastic diplegia frequently diagnosed as cerebral palsy.

The dominant laboratory findings are hyperammonemia and respiratory alkalosis, even though the clinical reliability of the latter has been questioned.[7] Plasma amino acids and urine orotic acid levels are necessary for a differential diagnosis.[18] High glutamine and alanine concentrations are typical, but not diagnostic for these disorders, reflecting an imbalance of the intracellular nitrogen pool. However, if the concentration of citrulline is low or undetectable, the overall profile is consistent with either OTC deficiency or CPS deficiency. These two have been differentiated by testing orotic acid in urine, which is elevated only in OTC deficiency. A more than twentyfold increase of the citrulline concentration indicates a defect at the level of argininosuccinic synthase, a condition commonly known as citrullinemia. A twofold to fivefold elevation of plasma citrulline in the presence of argininosuccinic acid in urine is indicative of argininosuccinase deficiency, but could also be indicative of other conditions (e.g., pyruvate carboxylase deficiency).

Acute hyperammonemia should be treated promptly as a medical emergency. A variety of conjugating agents (benzoate, phenylacetate, phenylbutyrate) are used to deplete the nitrogen pool via excretion of their glycine and glutamine conjugates.[72] Citrulline and/or arginine supplementation are used to provide substrates to the urea cycle downstream of specific blocks; neomycin and lactulose reduce the production of ammonia by intestinal bacteria. If these therapies along with the reversal of catabolism fail to effectively reduce blood ammonia within hours, dialysis (hemodialysis or peritoneal dialysis) must be instituted.

Nonketotic Hyperglycinemia

The large endogenous pool of glycine is maintained by dietary intake (3 to 5 g per day) and synthesis from serine, and provides approximately a fourth of the amino acid residue incorporated in major structural proteins. Glycine is also a precursor in the synthesis of purines, glutathione, creatine, and porphyrins. The enzyme glycine *N*-acyltransferase forms glycine conjugates of many acyl-CoA species that accumulate in the mitochondrial matrix in disorders of organic acid and fatty acid metabolism.[45] Glycine is catabolized by the glycine cleavage system, a four peptide complex (protein P, H, T, and L) attached to the inner membrane of mitochondria in liver, brain, kidney, and placenta. One carbon is converted to carbon dioxide, the other is transferred to tetrahydrofolate to from hydroxymethyltetrahydrofolate, which may either react with another mole of glycine to produce serine or form methyltetrahydrofolate, which serves as a methyl donor.

Nonketotic hyperglycinemia (NKHG) is a severe condition caused, in most cases, by a defect of either the T or P protein of the glycine cleavage system. In the newborn period, poor feeding, failure to suck, lethargy, and profound hypotonia rapidly progress to coma and death, which occur during the first few days of life. Intractable seizures and hiccups are common. The EEG pattern is characteristic with bursts of high complex waves of 1 to 3 seconds arising periodically from a hypoactive background, called burst-suppression pattern.[77] In infantile NKHG, symptoms, usually seizures, develop after 6 months of age. Late onset NKHG is a poorly defined entity reported only in a few patients with progressive spastic paraparesis, optic atrophy, and choreoathetoid movements. In the United States, screening NKHG is included in 7 state programs, corresponding to 8% of all babies born each year.

A key element that should raise the suspicion of NKHG is the finding of uninformative routine laboratory investigations in a child with progressing neurological symptoms. Plasma and CSF amino acid analysis reveal a high concentration of glycine (plasma>1000 μmol/L; CSF >30 μmol/L) with no other notable abnormalities (Figure 55-6, *E*), and urine organic acids are unremarkable. The calculated CSF: plasma glycine concentration ratio (NKHG: >0.09, reference intervals: <0.04) is critical in the differential diagnosis of this condition,[128] but caution should be used to avoid measuring the ratio when the plasma and CSF specimens were not collected simultaneously (no more than 1 hour apart). Contamination of CSF with blood could increase the concentration of glycine, but when it occurs, other unrelated amino acids are also elevated.

No effective treatment is known. Drugs that counteract the effect of glycine on neuronal cells, such as strychnine, diazepam, and dextromethorphan, could bring mild benefits in milder forms of the condition. Ketamine, an anesthetic blocker of the N-methyl-D-aspartate (NMDA) receptor channel, brought a partial improvement of neurological symptoms and EEG findings in some patients, but their developmental milestones were delayed.

DISORDERS OF ORGANIC ACID METABOLISM

Organic acids are water-soluble compounds containing one or more carboxyl groups and other functional groups (-keto, -hydroxy), which are intermediate metabolites of all major groups of organic cellular components: amino acids, lipids, carbohydrates, nucleic acids, and steroids. Organic acidurias are a biochemically heterogeneous group of inborn errors of

metabolism biochemically characterized by the accumulation of either (1) metabolites, which are not present under physiological conditions, from the activation of alternative pathways in response to the loss of function of a specific gene product, or (2) pathological amounts of normal metabolites.[26,48,68,127]

Table 55-3 shows a summary of known disorders of organic acid metabolism, including information about their incidence, major clinical features and biochemical patterns, availability of prenatal diagnosis and newborn screening, and association with sudden unexpected death. The incidence of individual inborn errors of organic acid metabolism varies from 1:10,000 to >1:1,000,000 live births. All possible disease entities included, the incidence of conditions in which informative organic acid profiles could be detected in urine is likely to approach 1:1000 live births.

The biochemical diagnosis of individual organic acidemias ultimately relies on urine organic acid analysis by gas chromatography-mass spectrometry (GC-MS).[43] Detection, positive identification, and eventually quantitation of pathognomonic organic acids by GC-MS could be available in a matter of hours if the analysis is performed at a local laboratory. Otherwise, results from a referral laboratory should be available within 24 hours for an urgent case. Informative profiles may not always be detected in disorders in which the excretion of diagnostic metabolites depends on the residual activity of the defective enzyme, the dietary load of precursors, and the anabolic status of a patient.

Several selected disorders of organic acid metabolism are discussed below.

Disorders of Propionate Metabolism

Propionyl-CoA is an intermediary product in the metabolism of four essential amino acids (isoleucine, valine, threonine, and methionine), the aliphatic side-chain of cholesterol, pyrimidines (uracil and thymine), and the final product of the β-oxidation of odd-chain fatty acids. Under normal circumstances, propionyl-CoA first is converted by a biotin-dependent carboxylase to methylmalonyl-CoA, then to succinyl-CoA by an adenosylcobalamin-dependent mutase, leading to oxidation in the tricarboxylic acid cycle.[38] Primary or secondary defects of these two enzymes were among the first organic acidurias to be discovered, and their natural history has been characterized perhaps better than any other inborn error of organic acid metabolism.

Propionic acidemia (PA) and methylmalonic acidemia (MMA) are panethnic disorders, but their combined incidence varies considerably, with estimates ranging from 1:2000 to 1:5000 (Saudi Arabia) to 20 times lower. However, there is a general consensus that many patients with this disorder die undiagnosed, being masked by a variety of catastrophic processes (sepsis and intraventricular hemorrhage).[97] In the United States, screening for these disorders by means of MS/MS detection of propionylcarnitine is not offered in 31 states, corresponding to 69% of all babies born each year. Curiously the state of Missouri has mandated screening for PA only.

Patients with PA and MMA typically are born at term with no pregnancy complications and present with an intoxication type of picture after hours or even days without apparent symptoms. Prominent manifestations include vomiting, hypotonia, lethargy, apnea, hypothermia, and rapid onset of coma. Routine laboratory investigations show severe metabolic acidosis and ketonuria (a finding of critical significance never to be overlooked in the newborn period); lactic acidemia, hypoglycemia, and hyperammonemia are often present[118]; the latter could be so severe as to direct the diagnostic work-up toward a urea cycle defect and not include urine organic acid analysis. Similarly, neutropenia caused by growth inhibition of myeloid progenitors is a common finding that in many cases is attributed to a primary immunodeficiency. Acute and chronic pancreatitis have also been observed in several patients with methylmalonic acidemia and other inborn errors of branched-chain amino acid metabolism.[60]

Hyperglycinemia is found when samples from affected patients are analyzed for plasma amino acids. In addition, the urine organic acid profile from a sample from an acutely affected individual could reveal lactic aciduria, ketonuria, and a large number of propionate metabolites, particularly 3-hydroxypropionic acid and 2-methylcitric acid. The glycine conjugates propionylglycine and tiglylglycine could be markedly elevated, and the latter could be confused with 3-methylcrotonylglycine (Figure 55-10), a distinction that is critical for the correct differential diagnosis between PA and multiple carboxylase deficiency. The presence or absence of methylmalonic acid is the main difference between PA and MMA (Figure 55-11, *A* and *B*). Although this is an easy distinction in most cases, a relatively small excretion of methylmalonic acid is actually possible in early stages of an acute episode,[109] and other factors may also lead to an incorrect differential diagnosis between these disorders.[34,35] In plasma, the concentration of propionylcarnitine is markedly elevated in PA and MMA caused by either one of the apoenzyme defects, and marginal elevations could be observed in patients with a coenzyme defect (various *cbl* complementation groups).

Patients who survive the initial event have developmental delay, hypotonia or hypertonia, and variable cognitive and neurological sequelae that are linked to the number and severity of acute episodes. Early detection seems to improve the prognosis; treatment is based on restriction of precursor amino acid intake, carnitine, and cofactors—biotin or cobalamin—as indicated.

Isovaleric Acidemia

Isovaleric acidemia (IVA) is a disorder of leucine catabolism caused by a deficiency of isovaleryl-CoA dehydrogenase. Since the initial report 40 years ago, IVA has been the main focus of the work of Dr. Kay Tanaka, one of the pioneers and arguably most productive contributors to our current

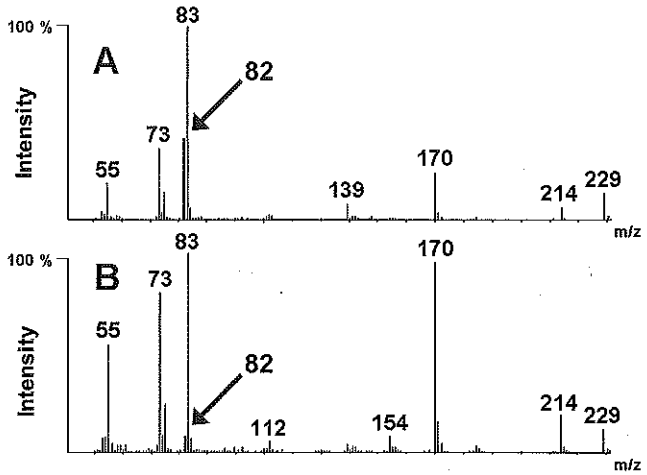

Figure 55-10 Electron impact positive ion mass spectra of isomeric acylglycines detected by GC/MS analysis of organic acid trimethylsilyl (TMS) derivatives. **A,** 3-Methylcrotonylglycine mono-TMS ester (leucine metabolism). **B,** Tiglylglycine mono-TMS ester (isoleucine metabolism). As their retention times are relatively close in most chromatographic systems, proper differentiation between the two compounds is best achieved by evaluation of the fragment ion at m/z 82 *(arrow)* which is prominent in the spectrum of 3-methylcrotonylglycine but not tiglylglycine.

The symbol * marks the internal standard (pentadecanoic acid), signal abundance is normalized to the intensity of the internal standard peak. Note: The peak legend also applies to Figure 54-12.

understanding of inborn errors of organic acid metabolism. His seminal work on IVA was particularly significant for the first application of GC-MS to the study of an IEM, and for the recognition and later complete characterization of a previously unknown enzyme on the basis of the biochemical phenotype found in patients with an inherited defect at that level.[129] In the United States, screening by means of MS/MS detection of isovalerylcarnitine is not offered in 35 states, corresponding to 69% of all babies born each year.

The clinical presentation of the neonatal form is similar to disorders of propionate metabolism. One revealing feature of this IEM is the characteristic odor of "sweaty feet." This feature is difficult to miss, but occasionally is absent or attributed to other causes. In practice, the diagnosis is confirmed by the specific pattern of excretion of organic acids with isovalerylglycine accumulating as the major by-product followed by 3-hydroxyisovaleric acid (Figure 55-11, *C*). In plasma, C5-acylcarnitine is elevated, but is actually a mixture of isovalerylcarnitine and 2-methylbutyrylcarnitine derived from leucine and isoleucine degradation, respectively.[79] Also the differential diagnosis has been further complicated by another C5 isomer, pivaloylcarnitine, which is formed in patients treated with antibiotics containing pivalic acid.[1] Initially, it was thought that IVA was an easily recognizable disorder at any clinical stage because of the magnitude of accumulation of isovalerylglycine and isovalerylcarnitine. However, this has been recently questioned by a number of cases detected by newborn screening in which several infants had much milder, even intermittent accumulation of

Acidosis, hemolytic anemia, neutropenia	Pyroglutamic (U)	Enzyme assay in amniocytes/CVS, pyroglutamic (AF), DNA analysis	8/51 states (9%)	/
Hyper IgD and periodic fever	Mevalonic, mevalonolactone (U)	Enzyme assay in amniocytes, mevalonic (AF)	Not available	/

diagnostic metabolites. Treatment with a low protein diet and glycine (250 mg/kg/day) and carnitine (50 mg/kg/day) supplements allows for a good prognosis, but acute episodes of metabolic decompensation could be life threatening at any age.

Glutaric Acidemia Type I

Glutaric acidemia type I (GA-I) results from an inherited defect in glutaryl-CoA dehydrogenase, an enzyme involved in the degradation of lysine and tryptophan. Affected individuals present with very severe but preventable neurological consequences and unpredictable variability of the biochemical phenotype. Characteristic clinical findings are macrocephaly and frontal bossing, sometimes present at birth, and the sudden onset of an encephalopathic episode usually before 3 years of age. Brain imaging of affected individuals demonstrates frontotemporal atrophy, and after a crisis the characteristic sequelae of acute striatal degeneration and shrinkage of the caudate and nucleate nuclei of the basal ganglia. Hypotonia, abnormal movements, seizures, hypoglycemia, and hepatomegaly have also been associated with acute events. In the United States, screening for GA-I by means of MS/MS detection of glutarylcarnitine is not offered in 31 states, corresponding to 69% of all babies born each year.

The classic biochemical phenotype consists of massive glutaric aciduria with increased concentrations of glutarylcarnitine in plasma. Increased concentrations of glutarylglycine are inconsistently detected in humans, even though it is readily detected in the GA-I mouse knockout model.[65] The typical pattern in urine and plasma is abnormal and many cases present with minimal excretion of metabolites and normal plasma acylcarnitines. Evaluation of glutarylcarnitine and glutarylglycine in urine could aid in the interpretation of inconclusive findings. It is not known what impact this variability may have on the sensitivity and specificity of newborn screening for GA-I by acylcarnitine analysis, but false-negative results are likely to occur.

Ethylmalonic Encephalopathy

Ethylmalonic encephalopathy (EE) is an autosomal recessive disorder originally reported in Italian families.[20] EE patients described thereafter have been of Mediterranean[42] or Arabic[98] descent, with a few exceptions.[142] The first group of patients to be reported presented with (1) neonatal hypotonia, (2) progressive pyramidal dysfunction, (3) mental retardation, (4) orthostatic acrocyanosis with distal swelling, (5) chronic diarrhea, (6) recurrent petechiae, and (7) abnormal brain MRI, showing symmetrical lesions of the caudate and lenticular nuclei. Other manifestations later recognized in additional patients are retinal lesions and hematuria. In addition to persistent lactic acidemia, blood metabolite profiles include elevated C4 (predominantly isobutyryl-) and C5 acylcarnitine (2-methylbutyryl-) species. In urine, excretion of high concentrations of ethylmalonic acid is the most consistent finding, in association with elevated excretion of

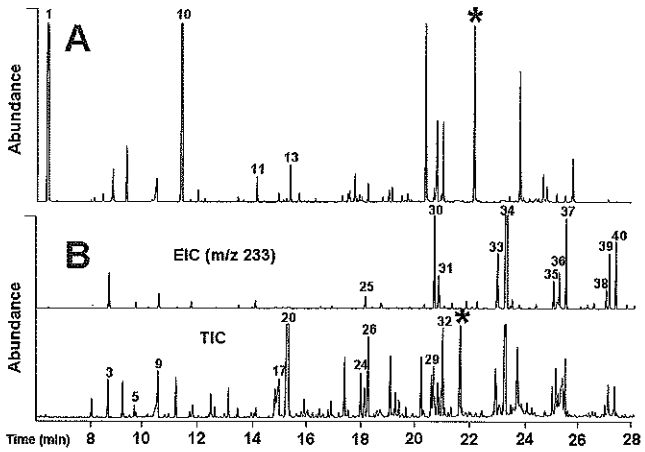

Figure 55-12 Partial urine organic acid profiles (7-28 minute portion of a 33 minute run). **A,** Ethylmalonic encephalopathy. **B,** LCHAD deficiency. The top section shows the extracted ion chromatogram (EIC) of m/z 233, the signature fragment of 3-hydroxy acid TMS-esters. Peak legend as in Figure 55-8. The symbol * marks the internal standard (pentadecanoic acid), signal abundance (total ion current, TIC) is normalized on the intensity of the internal standard peak. EIC abundance was set arbitrarily for better graphic display.

isobutyrylglycine, 2-methylbutyrylglycine, and other C4-C6 glycine esters (Figure 55-12, *A*). Ethylmalonic acid derives from either the carboxylation of butyryl-CoA, in disorders of β-oxidation of short-chain fatty acids, or from 2-ethylmalonic-semialdehyde, the final product of the R-pathway catabolism of isoleucine.[75]

Although the combination of these findings is indicative of a generalized impairment of multiple mitochondrial acyl-CoA dehydrogenase enzymes, extensive studies have failed to unveil the specific underlying defect. However, the gene locus of EE was identified in 2004,[132] but the function of the gene product, a mitochondrial protein, remains to be elucidated. It is likely that this discovery will lead to a better understanding of the natural history of the disorder, and possibly uncover evidence that its incidence could have been significantly underestimated, because the biochemical phenotype was incorrectly attributed to other metabolic disorders, particularly defects of the mitochondrial electron transfer flavoprotein pathway.

DISORDERS OF FATTY ACID OXIDATION

Long-chain fatty acids are involved in a wide variety of cellular processes, including (1) phospholipid synthesis, (2) protein posttranslational modifications, (3) cell signaling, (4) membrane permeability, and (5) transcription control.[36] Yet the most critical function is to sustain energy production during fasting or periods of higher energy demands via mitochondrial β-oxidation. Once mobilized from adipose tissue, fatty acids are taken up by liver and muscle cells via an active transport system.[10] After activation to their respective coenzyme A (CoA) esters by ATP-dependent acyl-CoA

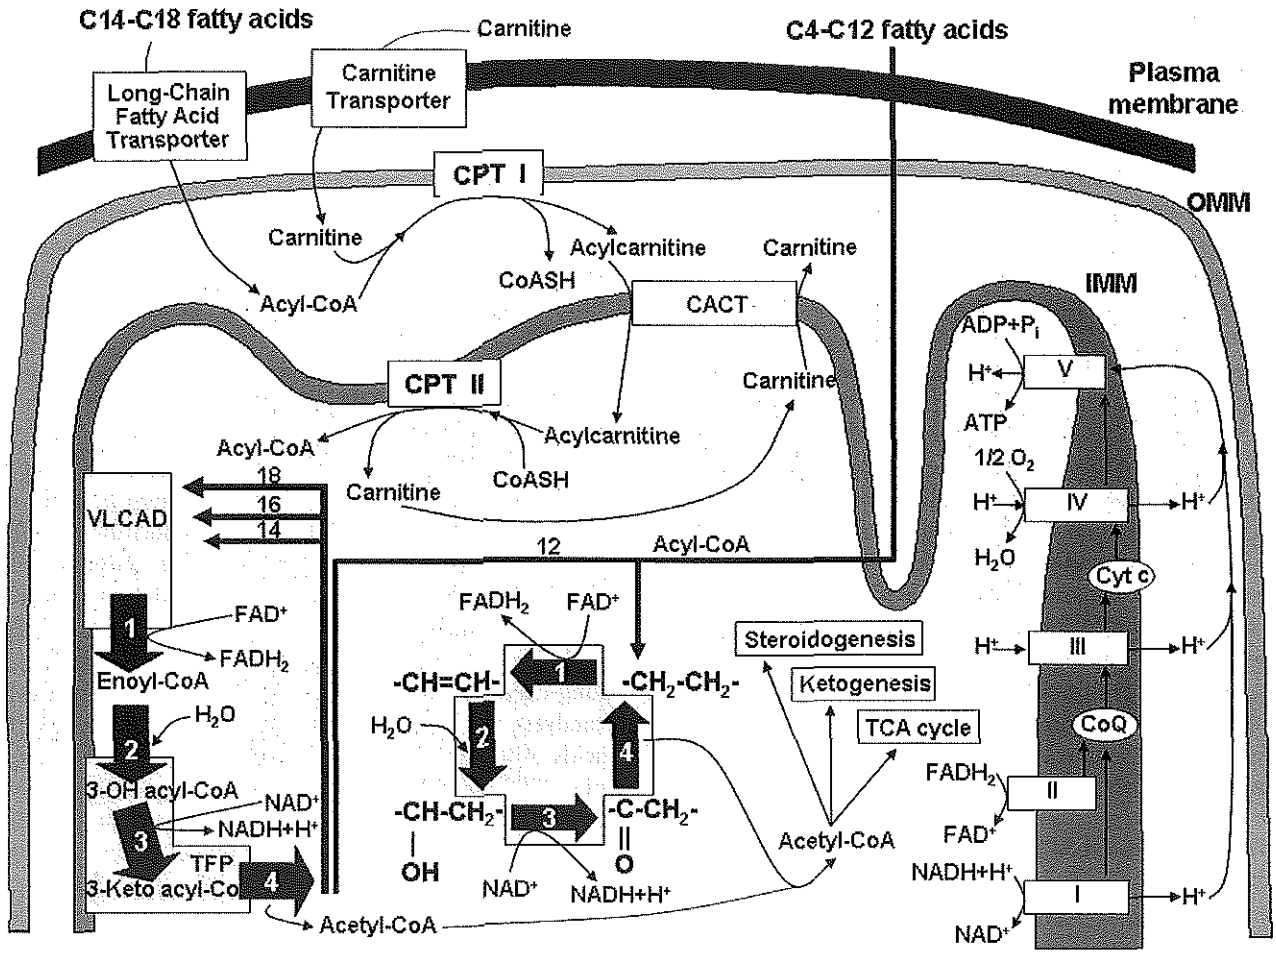

Figure 55-13 Pathway of fatty acid metabolism from the transport of long-chain fatty acids and carnitine across the plasma membrane to the production of acetyl-CoA. Medium- and short-chain fatty acids do not require an active transport mechanism to reach the mitochondrial matrix. Enzymes of the carnitine cycle (CPT I, CACT, and CPT II) shuttle long-chain fatty acids across the mitochondrial membranes. The fatty acid β-oxidation spiral includes (1) an FAD-dependent acyl-CoA dehydrogenase step followed by (2) a 2,3-enoyl-CoA hydratase reaction, (3) the NAD-dependent 3-hydroxyacyl-CoA dehydrogenase step, (4) and the thiolase cleavage reaction. Oxidation of long-chain fatty acids (membrane-bound enzymes) and medium-/short-chain fatty acids (matrix) is shown separately. Reducing equivalents ($FADH_2$ and $NADH+H^+$) are directed to the oxidative phosphorylation pathway (*right*). *CACT,* Carnitine:acylcarnitine translocase; *CPT,* carnitine palmitoyltransferase; *IMM,* inner mitochondrial membrane; *OMM,* outer mitochondrial membrane; *TCA,* tricarboxylic acid; *TFP,* trifunctional protein; *VLCAD,* very-long chain acyl-CoA dehydrogenase. *(From Rinaldo P, Matern D, Bennett MJ. Fatty acid oxidation disorders. Ann Rev Physiol 2002;64:477-502.)*

synthetases, fatty acids are transported into mitochondria by a series of three membrane-bound enzymes that temporarily convert the acyl-CoA into an acylcarnitine species before delivering a reconstituted fatty acyl-CoA into the inner mitochondrial space (Figure 55-13).[84] Medium- and short-chain fatty acids enter the mitochondria independently of the so-called carnitine cycle and are activated within the mitochondrial matrix by different acyl-CoA synthetases.

Enzymes with affinity for long-chain species of fatty acids are associated with the inner mitochondrial membrane while the enzymes responsible for the metabolism of medium- and short-chain species are located within the mitochondrial matrix. Fatty acids are oxidized to their final product, acetyl-CoA, in a cyclic fashion, which consists of four sequential reactions mediated by highly homologous enzymes.[37] These enzymes are characterized by their affinity for substrates of decreasing chain length, hence the common nomenclature using prefixes, such as very long-chain, long-chain, medium-chain, and short-chain. The catalytic activities of these enzymes are FAD-dependent acyl-CoA dehydrogenase, enoyl-CoA hydratase, NAD-dependent L-3-hydroxyacyl-CoA dehydrogenase, and ketoacyl-CoA thio-

lase, respectively, and in sequential order (Figure 55-13). Each cycle of the pathway produces a molecule of acetyl-CoA and a fatty acid with two fewer carbons. Under physiological conditions, the latter reenters the cycle until it is completely consumed (see Chapter 26). In the muscle, acetyl-CoA is directly used as energy substrate for the citric acid cycle, whereas in the liver it constitutes the building block for the synthesis of ketone bodies (acetoacetic acid and D-3-hydroxy butyric acid), which serve as fuels for production of energy in other tissues when the supply of glucose is depleted (see Chapter 25).

Inherited FAO disorders represent a rapidly expanding class of metabolic diseases.[111] Symptoms may appear at any age, from birth to adult life, frequently leading to life-threatening episodes of metabolic decompensation after a period of inadequate caloric intake and/or intercurrent illness. Typical manifestations are hypoketotic hypoglycemia, liver disease, cardiomyopathy, and sudden death. Table 55-4 shows a summary of known disorders of fatty acid transport and mitochondrial oxidation, including information about their incidence, major clinical features and biochemical patterns, availability of prenatal diagnosis and newborn screening, and association with sudden and unexpected death.

Selected fatty acid oxidation disorders are discussed in the following sections.

Very Long-Chain Acyl-CoA Dehydrogenase Deficiency

Very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency is an autosomal recessive condition. In the mid 1980s, patients with VLCAD deficiency were initially described as having long-chain acyl-CoA dehydrogenase (LCAD) deficiency.[47] However, without exception, once the VLCAD protein was identified,[5] affected patients were shown to have no detectable VLCAD protein by immunoblot analysis[141] or to harbor disease-causing mutations in the VLCAD gene.[123]

VLCAD catalyzes the first step of the fatty acid β-oxidation spiral. The severity of the phenotype appears to correlate with specific genotypes.[4] The most severe phenotype manifests early in life and is associated with nonsense mutations resulting in complete loss of enzyme activity. Morbidity and mortality are significant because of involvement of multiple organ systems, in particular liver and heart, resulting in recurrent metabolic crises and cardiomyopathy.[81] Patients carrying missense mutations or with single amino acid deletions permitting some residual enzyme activity are at high risk of metabolic decompensation with nonketotic hypoglycemia and a Reye's-like syndrome (see Chapter 47) triggered by increased energy demands (prolonged fasting, fever, etc.). As patients become older, the phenotype switches from a more hepatic presentation to muscle weakness. Some patients are able to sustain metabolic stress during childhood and do not present until adulthood with exercise-induced myopathy and rhabdomyolysis.

Laboratory indicators during acute episodes include hypoketotic hypoglycemia and creatine kinase elevations. Urine organic acid analysis is nonspecific with hypoketotic dicarboxylic aciduria. Acylcarnitine analysis is most informative, revealing a characteristic profile with elevated levels of saturated and unsaturated C14 to C18 carnitine esters, the predominant species being tetradecenoylcarnitine (C14:1) (Figure 55-14, *F*).[85] The diagnosis is confirmed by specific enzyme assay or fatty acid oxidation in vitro, by probing in fibroblast cultures,[116] or by molecular genetic analysis of the VLCAD gene.

Trifunctional Protein and Long-Chain 3-Hydroxy Acyl-CoA Dehydrogenase Deficiencies

The trifunctional protein (TFP) is a hetero-octamer containing four α- and four β-subunits encoded by two different genes.[21] The α-subunit harbors the activities of the second and third step of fatty acid β-oxidation, long-chain enoyl-CoA hydratase (LCEH) and long-chain 3-hydroxy acyl-CoA dehydrogenase (LCHAD). The β-subunit harbors long-chain 3-ketoacyl-CoA dehydrogenase (LCKAT), which catalyzes the last step in β-oxidation of long-chain fatty acids. Although mutations in either gene may cause complete TFP deficiency,[57,138] a few mutations in the α-subunit cause isolated LCHAD deficiency.[54] A genotype-phenotype correlation has also emerged for TFP deficiency, with residual enzyme activity being associated with a milder, later onset phenotype. Patients with late onset TFP deficiency present with a progressive peripheral neuropathy and episodic rhabdomyolysis.[124] While the phenotype of both disorders includes all the symptoms expected in an FAO disorder, patients with LCHAD/TFP deficiencies may also develop pigmentary retinitis and a peripheral neuropathy, whose pathophysiology remains obscure. In addition, many patients are born prematurely and small for gestational age.[80]

Patients with isolated LCHAD deficiency have a reduction in LCHAD activity with normal LCEH and LCKAT activities.[56] The most common cause of isolated LCHAD deficiency is the 1528G>C mutation that changes a glutamate to a glutamine residue (E474Q) in the active site of the α-subunit of the LCHAD gene.[53] The replacement of the acidic residue with a neutral amide amino acid is thought to involve the NAD^+-binding site of the enzyme and subsequently results in an isolated reduction of LCHAD activity without affecting the activities of LCEH and LCKAT.

Another feature that was thought to be specific to LCHAD deficiency was the observation that approximately 20% of patients were born following pregnancies complicated with maternal liver disease, in particular acute fatty liver of pregnancy (AFLP)[52] and the syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP).[126] However, several other FAO disorders have meanwhile been implicated as possible triggers of maternal liver disease during pregnancy.[111]

The biochemical diagnosis of TFP/LCHAD is based on the finding of hypoketotic C6-C10 dicarboxylic aciduria and

TABLE 55-4 Clinical and Laboratory Characteristics of Fatty Acid Oxidation Disorders

Common Name	OMIM No.	Enzyme/Transport Defect	Incidence (USA)	Major Clinical Features	Complication of Pregnancy (Maternal, Fetal)
Long-chain fatty acid uptake defect	603376	/	<1:100,000	Liver disease	/
Carnitine uptake defect	212140	Carnitine transporter	<1:100,000	Hypoglycemia, cardiomyopathy	/
CPT-I deficiency (liver and muscle types)	255120 600528 601987	Carnitine palmitoyl transferase I	<1:100,000	Liver disease, hypotonia, renal tubular acidosis	AFLP
Translocase deficiency	212138	Carnitine acylcarnitine translocase	<1:100,000	Cardiomyopathy, liver disease	Pre-eclampsia
CPT-II deficiency	600649 600650	Carnitine palmitoyl transferase II	<1:100,000	Cardiomyopathy, liver disease, congenital anomalies. Adult onset myopathy.	/
VLCAD deficiency	201475	Very long-chain acyl-CoA dehydrogenase	>1:75,000	Spectrum from early onset cardiomyopathy, coma, liver disease to adult onset myopathy	/
LCHAD deficiency	600890	Long-chain 3-hydroxyacyl-CoA dehydrogenase	>1:75,000	Cardiomyopathy, liver disease, retinopathy, peripheral neuropathy	AFLP, HELLP syndrome, preeclampsia, placental floor infarction
TFP deficiency	600890 143450	Trifunctional protein	<1:100,000	Cardiomyopathy, liver disease, retinopathy, peripheral neuropathy	AFLP, HELLP syndrome
Glutaric acidemia type II	231680 130410 231675	Electron transfer flavoprotein (ETF), ETF ubiquinone oxidoreductase	<1:100,000	Cardiomyopathy, liver disease, congenital anomalies. Adult onset myopathy.	/
MCAD deficiency	201450	Medium-chain acyl-CoA dehydrogenase	>1:25,000	Liver disease	HELLP syndrome
M/SCHAD deficiency	601609	Medium/short-chain 3-hydroxyacyl-CoA dehydrogenase	<1:100,000	Liver disease	/
MCKAT deficiency	602199	Medium-chain 3-ketoacyl-CoA thiolase	<1:100,000	Cardiomyopathy, liver disease	/
SCAD deficiency	201470	Short-chain acyl-CoA dehydrogenase	>1:50,000	Developmental delay, hypotonia, seizures	AFLP, HELLP syndrome
SCHAD deficiency	601609	Short-chain 3-hydroxyacyl-CoA dehydrogenase	<1:100,000	Hypoglycemia, liver disease	/
Dienoyl-CoA reductase deficiency	222745	Dienoyl-CoA reductase	<1:100,000	Myopathy	/

OMIM, Online Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM); *NBS,* newborn screening; *AFLP,* acute fatty liver of pregnancy; *HELLP syndrome,* hemolysis, elevated liver enzymes, and low platelet count.

Modality of Acute Episodes	Major Biochemical Marker(s)	Prenatal Diagnosis	NBS in the US (% Births)	Sudden Unexpected Death
Acute liver failure	Low long-chain fatty acids (Liver)	Not reported	Not available	Anecdotal reports
Fasting intolerance, hypoketotic hypoglycemia	Low free carnitine (B)	Enzyme assay in amniocytes, DNA analysis	1/51 states (2%)	Frequent
Fasting intolerance, hypoketotic hypoglycemia	High free carnitine (B)	Enzyme assay in amniocytes/CVS and molecular genetics	12/51 states (16%)	Frequent
Fasting intolerance, hypoketotic hypoglycemia	C16/C18 acylcarnitines (B)	Enzyme assay in amniocytes, DNA analysis	15/51 states (25%)	Frequent
Fasting/exercise/cold intolerance, myoglobinuria	C16/C18 acylcarnitines (B)	Enzyme assay in amniocytes, DNA analysis	8/51 states (29%)	Not reported
Hypoketotic hypoglycemia, myoglobinuria	C14:1 acylcarnitine (B)	Enzyme assay in amniocytes, DNA analysis	20/51 states (32%)	Frequent
Hypoketotic hypoglycemia, myoglobinuria	C16-OH/C18-OH acylcarnitines (B); C6-C14 3-OH dicarboxylic acids (U)	Enzyme assay in amniocytes, DNA analysis	21/51 states (31%)	Frequent
Hypoketotic hypoglycemia, myoglobinuria	C16-OH/C18-OH acylcarnitines (B); C6-C14 3-OH dicarboxylic acids (U)	Enzyme assay in amniocytes, DNA analysis	15/51 states (25%)	Frequent
Fasting intolerance, hypoketotic hypoglycemia	C4 to C18 acylcarnitines (B); C5-C10 dicarboxylics, ethylmalonic, C4-C8 acylglycines (U)	Enzyme assay in amniocytes, glutaric C4 C5 acylcarnitines (AF), DNA analysis	18/51 states (29%)	Frequent
Fasting intolerance, hypoketotic hypoglycemia	C6, C8 and C10 acylcarnitines (B); hexanoylglycine, suberylglycine, phenylpropionylglycine (U)	Enzyme assay in amniocytes, DNA analysis	29/51 states (53%)	Frequent
Fasting intolerance, hypoketotic hypoglycemia	C6-C10 3-OH fatty acids (B)	DNA analysis	1/51 states (2%)	Anecdotal reports
Fasting intolerance, hypoketotic hypoglycemia	C6-C12 dicarboxylic acids (U)	Not reported	3/51 states (5%)	Anecdotal reports
Hypoglycemia	Butyrylcarnitine (B); ethylmalonic methylsuccinic butyrylglycine (U)	Enzyme assay in amniocytes, DNA analysis	28/51 states (51%)	Anecdotal reports
Ketotic hypoglycemia	Ketosis 3-OH fatty acids (B); 3-OH dicarboxylic acids (U)	Not reported	3/51 states (4%)	Frequent
/	2-trans,4-cis-decadienoylcarnitine	Not reported	5/51 states (8%)	Not reported

C6-C14 3-hydroxydicarboxylic aciduria (Figure 55-11, *F*) with prominent unsaturated species, and elevated plasma concentrations of C16-OH and C18-OH acylcarnitine species (Figure 55-14, *G*). These metabolites could not be found in specimens collected when patients are clinically asymptomatic.

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

MCAD deficiency is responsible for the initial dehydrogenation of acyl-CoAs with a chain length between 4 and 12 carbon atoms. First reported in 1982, MCAD deficiency is frequently diagnosed in previously healthy children who present with hypoketotic hypoglycemia, vomiting, and lethargy triggered by a common illness, which quickly progress to coma and death. Hepatomegaly and acute liver disease are often present. Affected individuals typically present between 3 and 24 months of age; later presentation, even into adulthood, is possible.[15,105] The prognosis is excellent once the diagnosis is established and frequent feedings are instituted to avoid any prolonged period of fasting. It is unfortunate that only half of the babies born in the United States are currently screened for this disorder.

Early diagnosis is crucial, because MCAD deficiency is a potentially lethal disease, documented by the fact that up to at least 20% of undiagnosed patients die during their first metabolic decompensation.[51] A common missense mutation (985A>G; K304E) has been identified in Caucasians of Northern European descent,[82] which results in reduced production of an unstable protein.

A defect of the MCAD enzyme leads to accumulation of medium-chain fatty acids, which are conjugated with either carnitine or glycine.[113] Analysis of plasma acylcarnitines by MS/MS reveals accumulation of C6 to C10 acylcarnitine species, with prominent concentration of octanoylcarnitine (Figure 55-14, *E*).[135] A potential pitfall of acylcarnitine analysis in the diagnosis of MCAD deficiency and other FAO disorders is the possibility that patients with secondary carnitine deficiency may not have a significant elevation of C6-C10 acylcarnitine concentrations.[30] Hexanoylglycine, phenylpropionylglycine, and suberylglycine are consistently detected in urine of asymptomatic patients and represent the most sensitive and specific markers of the disease, but are frequently overlooked by standard organic acid analysis. Proper detection of acylglycines at concentrations of excretion below 10 mmol/mol creatinine requires a different derivatization process (methylation or butylation) and quantitation using stable-isotope labeled internal standards.[113] A biochemical diagnosis of MCAD deficiency is confirmed by measurement of the activity of the MCAD enzyme in fibroblasts and other tissues and by molecular genetic testing of the *ACADM* gene; both test methods have been used for prenatal diagnosis.

Detection of C6-C10 acylcarnitines in neonatal blood spots by MS/MS is the basis for newborn screening of MCAD deficiency.[23] Identification of numerous patients by newborn screening has led also to the discovery of patients with only mild biochemical abnormalities and significant residual enzyme activity in vitro.[2,3,144] Whether patients with such genotypes will remain asymptomatic, even during times of increased energy demands, remains to be determined either by long-term follow-up or by carefully conducted fasting challenges.

Short-Chain Acyl-CoA Dehydrogenase Deficiency

First reported in 1984, 133 individuals with short-chain acyl-CoA dehydrogenase (SCAD) deficiency present with a surprising variety of clinical phenotypes, ranging from catastrophic illness in the neonatal period to adult onset of skeletal myopathy.[11] Hypotonia, developmental delay, and seizures are relatively common findings,[32] underscoring the need of a metabolic work-up in patients presenting with nondescriptive phenotypes,[19] and also the benefits that universal newborn screening could bring to patients with this and many other IEM by reducing the length and costs of the medical odyssey many of them endure.

When the first step of the β-oxidation of butyryl-CoA is impaired, alternative metabolism takes place via carboxylation to ethylmalonic acid (EMA) mediated by propionyl-CoA carboxylase and conjugation with carnitine and glycine. The most useful biochemical markers of SCAD deficiency are therefore EMA and butyrylglycine in urine, and butyrylcarnitine in plasma (Figure 55-14, *C*). However, these findings still require a complex differential diagnosis. Butyrylcarnitine is measured by MS/MS together with isobutyrylcarnitine as total C4-species, and the two could be easily confused or misinterpreted.[64,98] The corresponding glycine conjugates, however, are readily separated and measured by GC-MS.[20,142]

EMA aciduria may be associated with several other inherited and acquired conditions, including (1) glutaric acidemia type II (some cases are actually labeled to have ethylmalonic adipic aciduria),[76] (2) disorders of the intramitochondrial flavin adenine dinucleotide pathway,[41] (3) mitochondrial respiratory chain disorders,[28,67] and (4) ethylmalonic encephalopathy.[20] Jamaican vomiting sickness (due to ingestion of unripe ackee fruit containing the poison hypoglycin A)[130] and ifosfamide treatment[66] represent two additional causes of ethylmalonic aciduria.

In vitro confirmation of SCAD deficiency is also challenging and should include both biochemical and molecular genetic studies. Fibroblasts have been used to first assess fatty acid oxidation of palmitate in whole cells and/or the specific SCAD activity using butyryl-CoA as substrate, followed by SCAD gene sequencing. However, while several pathogenic mutations have been identified, molecular genetic testing for SCAD deficiency may reveal only two SCAD gene variants, 625G>A (G185S) and 511C>T (R147W),[31,46] which occur in the homozygous or compound heterozygous state in 7% of the United States population.[94] Among patients with mild to moderate EMA aciduria, these variants are over-represented[31]; some patients with biochemical evidence of SCAD deficiency do not carry any other SCAD gene mutations.[32]

In vitro studies have shown that these variants compromise SCAD activity because of abnormal protein folding and thermolability, respectively.[100] In general, the two common variants are believed to confer disease susceptibility in combination with other genetic and environmental factors.

ANALYTICAL CONSIDERATIONS

Diagnosis of the disorders discussed above requires the analysis of amino acids, organic acids, and acylcarnitines. Further details of such analytical procedures are available on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/. Here, we briefly describe the assay principles.

Analysis of Amino Acids

Amino acids are quantitatively measured in plasma, urine, and CSF using a variety of techniques, which include capillary electrophoresis, gas-liquid chromatography, reversed phase high performance liquid chromatography (HPLC),[131] ion-exchange liquid chromatography,[121] and MS/MS (see Chapters 5, 6, 7, and 20).[25] Currently, ion exchange chromatography analysis of amino acids is the most widely used method to identify defects of amino acid metabolism. Screening methods, such as thin layer chromatography, that do not result in positive identification of all amino acids of clinical interest lead to errors and should be considered obsolete.

Ion Exchange Liquid Chromatography

Several amino acid analyzers are commercially available. With such analyzers, the sample is applied to a column of ion-exchange resin. Buffers of varying pH and ionic strength are pumped through the column at a constant rate. The individual amino acids are retained on the resin depending on their affinity to the resin. The eluate from the column is mixed with ninhydrin reagent, heated to 135 °C for color development, and monitored with a flow cell photometer at 440 nm (for imino acids) and at 570 (for amino acids). The sum of the absorbances at 440 and 570 is interfaced to a commercial software that stores, calculates, and prints the concentrations of the amino acids in reference to an internal standard. Peak identification is based on retention time, absolute and relative to the nearest internal standard; the 570/440 area ratio; and eventually spiking with the standard solution. Amino acids are quantified by comparing area peak ratios with those of an internal standard.

Sample Requirements

Fasting plasma (heparin) is the preferred specimen type. In newborns and infants blood should be collected immediately before the next scheduled feeding. Serum is generally derived from blood left to clot at room temperature, a process that leads to artifacts from deamination, loss of sulfur-containing amino acids due to protein binding, conversion of arginine to ornithine by red blood cell arginase, and release of oligopeptides. Hemolyzed specimens show higher concentrations of amino acids that are found in higher concentration in blood cells (taurine, aspartic acid, and glutamic acid).

Analysis of urine is indicated for the diagnosis of disorders affecting renal transport of one or more amino acids. Urine collection should avoid fecal contamination and the addition of preservatives. Although a 24-hour collection (kept refrigerated during collection) is necessary in a few clinical circumstances, it is rarely needed during the diagnostic work-up of a patient and should be avoided when a patient is acutely ill, especially when of pediatric age. Urine creatinine is used for normalization and the concentration ratio to creatinine is widely used in clinical practice. One potential problem could be encountered in the evaluation of patients with unrecognized disorders of creatine metabolism[55,117,137] in whom a low creatinine excretion leads to quantitative results suggestive of a general amino aciduria that is out of proportion with the magnitude of changes observed by visual inspection of the chromatogram. Cerebrospinal fluid (CSF) must be collected free of blood contamination.

Reference Intervals

Reference intervals for urine and plasma amino acids are listed in Table 56-2, Chapter 56.

Analysis of Organic Acids

Capillary gas chromatography-mass spectrometry is being used to separate and measure the trimethylsilyl (TMS) ethers of organic acids. A capillary GC column is used that contains an immobilized nonpolar stationary phase. Organic acids are detected by electron impact (EI) mass spectrometry performed in the scan mode m/z 50 to m/z 550 to obtain mass spectra. Identification is by comparison to a library of spectra generated by analysis of pure standard compounds integrated by published spectra, when applicable.

Sample Preparation

Organic acids (OA) are extracted from urine by liquid-liquid extraction. A volume of a random urine specimen corresponding to 0.25 mg of creatinine is used. For analysis, urine samples normalized to creatinine concentration are first mixed with the internal standard solution (100 µL). Then 2.5 mL of ethyl acetate are added and mixed vigorously before centrifugation for 1 minute. After transfer evaporation, organic acids present in the dry residue are converted to their corresponding TMS ethers by addition of 100 µL of BSTFA/1%TMCS, and allowed to react in a heating block for 30 minutes at 80 °C. After cooling at room temperature, specimens are analyzed.

Reference Intervals

Age-matched reference intervals of selected organic acids and acylglycines are listed in Table 55-5.

TABLE 55-5 Reference Intervals of Selected Organic Acids and Acylglycines in Urine (mmol/mol Creatinine)

Age Groups	0-1 Month	1-6 Months	6 Months-5 Years	>5 Years

Analysis of Acylcarnitines

Acylcarnitines are quantified by MS/MS, with their profiles playing a critical role in every clinical application of biochemical genetics: prenatal diagnosis, newborn screening, evaluation of symptomatic patients, and postmortem screening. As with other complex metabolic profiles, it is critical to complement analytical proficiency with in-depth interpretation of results and informative reporting.

Electrospray Tandem Mass Spectrometry

With electrospray ionization tandem mass spectrometry (ESI-MS/MS), the liquid sample is introduced into the ion source through a capillary tube and exposed to a strong electric field and a counter flow of nitrogen gas, which in combination produce the electrospray (see Chapter 7). The solvent evaporates and eventually desorption of charged ions occurs into the mass analyzer. ESI occurs under atmospheric

pressure, allowing efficient ionization, whereas the mass analyzers operate at very low pressure. The combination is possible by introducing the ions into the analyzers through a very small orifice (<1 mm) and using powerful vacuum pumps.

A data file is generated for all ions with precursors of m/z 85 within a mass range of m/z 250 to m/z 500. Profiling of acylcarnitines as $[M+H]^+$ molecular ions allows identification, automated calculation of quantitative and semiquantitative concentrations for each acylcarnitine species against the internal standards, and comparison with age-appropriate reference intervals.

Sample Requirements

Carnitine and its esters are physiologically present in all biological fluids. For diagnostic purposes, acylcarnitines were first measured in urine[87] until plasma/serum became the preferred specimen types in diagnostic settings[86,135] and blood dried on filter paper for newborn screening.[23] However, urinalysis could be valuable in the investigation of patients with inconclusive/borderline urine organic acid and plasma acylcarnitine profiles, and useful in the selection of further in vitro investigations. Bile is analyzed postmortem in the evaluation of cases of sudden and unexpected death.[104] Cell-free supernatant of amniotic fluid is used for the prenatal diagnosis of selected IEM.[114,134] All sample types, with the exception of blood and bile spots dried on filter paper, which can be sent at room temperature, should be kept frozen until analysis. Long-term storage at room temperature causes progressive losses; degradation of short-chain acylcarnitines happens faster than long-chain species.

Reference Intervals

Acylcarnitine reference intervals are listed for plasma in Table 55-6, for urine in Table 55-7, and for postmortem blood and bile in Table 55-8. The last two are calculated as the 5 to 95 percentile range of all postmortem cases previously investigated in our laboratory.

TABLE 56-1 Reference Intervals and Values

The results of laboratory tests have little practical utility until clinical studies have ascribed various states of health and disease to intervals of values. Reference intervals are useful because they attempt to describe the typical results found in a defined population of apparently healthy people. Different methods may yield different values, depending on calibration and other technical considerations. Hence, different reference intervals and results may be obtained in different laboratories. Variability among methods is particularly characteristic of methods that use antibodies to detect the material of interest and when results are reported as relative units of activity. Values from apparently "healthy" and diseased people may overlap significantly. Therefore reference intervals, although useful as a guideline for clinicians, should not be used as absolute indicators of health and disease (see Chapter 16). The reference intervals presented in this chapter are for **general informational purposes only.** Guidelines for defining and determining reference intervals have been discussed in Chapter 16 and published in the 2000 NCCLS C28-A2 guideline (How to Define and Determine Reference Intervals in the Clinical Laboratory; Approved Guideline—Second Edition.) As stated in several chapters in this textbook, individual laboratories should generate their own set of reference intervals.

Where both exist, reference intervals are listed in both conventional and international units and are for adults in the fasting state unless otherwise stated. Values for other age groups, when included, are clearly identified. Most of the values listed were obtained from chapters in this book. Some were extracted from Tietz NW. *Clinical guide to laboratory tests,* 3rd ed. Philadelphia: WB Saunders, 1995 and Burtis CA, Ashwood ER. *Tietz textbook of clinical chemistry,* 3rd ed. Philadelphia: WB Saunders, 1999. For several of the specific proteins, reference intervals—obtained after calibration of the analytical system with the international protein reference RPPHS/CRM-470—are listed in Chapter 20. Additional intervals can be found in Wu AH, ed. *Tietz clinical guide to laboratory tests,* 4th ed. Philadelphia: WB Saunders, In Press.

A valuable source for reference intervals for older methods is http://cclnprod.cc.nih.gov/dlm/testguide.nsf/ (Accessed February 19, 2005).

For convenience and to preserve space, we have used standard abbreviations commonly used in laboratory medicine. Less common abbreviations and some nonstandard abbreviations are given below:

Amf	Amniotic fluid
CSF	Cerebrospinal fluid
EDTA	Ethylenediaminetetraacetic acid
F^-	Fluoride ion
F^-/Ox	Fluoride ion & oxalate
Hep	Heparin
Occup. exp.	Occupational exposure
Ox	Oxalate
P	Plasma
Plt	Platelets
RBC	Red blood cells
S	Serum
Sal	Saliva
U	Urine
WB	Whole blood

TABLE 56-2 Therapeutic and Toxic Levels of Drugs

Therapeutic drug monitoring and detection of drug overdose have become increasingly important aspects of the laboratory's role in patient care. The information given for the drugs in this table has been gathered from published sources. Because knowledge and drug measurement methodologies are continuously improving, it may be necessary to supplement the information given here with information obtained from other sources as it becomes available. Reliable drug analysis information depends on a well coordinated sample collection, assay methodology characteristics, and patient-associated considerations such as age, disease state, concomitant drug administration, and clinical procedures that the patient may have undergone. In practice, each organization should have its own set of therapeutic and toxic levels for the drugs it measures.

Many tests for therapeutic drugs require careful timing between administration and sample collection if the measured drug level is to be of optimal use clinically. Therapeutic and toxic intervals for which definitive limits do not exist have been omitted from the table. Drugs are listed by their chemical or generic name, followed by a commercial brand of the drug (where appropriate).

For convenience and to preserve space, we have used standard abbreviations commonly used in laboratory medicine. Less common abbreviations and some nonstandard abbreviations are given below.

Abbreviation	Term
EDTA	Ethylenediaminetetraacetic acid
Hep	Heparin
Occup. exp.	Occupational exposure
P	Plasma
Prem	Premature
S	Serum
Therap	Therapeutic
U	Urine
WB	Whole blood

		Peak	>10		>21
		Trough	>2		>4
Glutethimide (Doriden)	S		µg/mL	4.60	µmol/L
		Therap	2-6		9-28
		Toxic	>5		>23
Haloperidol (Haldol)	S or P (Hep or EDTA)	Therap	ng/mL 1-10	2.66	nmol/L 2.7-26.6
Hydromorphone (Dilaudid)	S		ng/mL	3.50	nmol/L
		Therap	1-3		4-10.5
		Toxic	>100		>350
Ibuprofen (Motrin)	S or P (EDTA)		µg/mL	4.85	µmol/L
		Therap	10-50		49-243
		Toxic	>100		>485
Imipramine (Tofranil)	S or P (Hep or EDTA)		ng/mL	3.57	nmol/L
		Therap	150-250		536-893
		Toxic	>500		>1785
Indinavir (Crixivan)	S or P (Hep or EDTA)		µg/mL	1.41	µmol/L
		Therap			
		Trough	>0.1		>0.14
		Peak	8-10		11.3-14.1
		Toxic	>10		>14.1
Isoniazid (Hyzyd, Nydrazid)	S or P (Hep or EDTA)		µg/mL	7.29	µmol/L
		Therap	1-7		7-51
		Toxic	>20		>146
Kanamycin (Kantrex)	S or P (EDTA)		µg/mL	2.06	µmol/L
		Therap			
		Peak	25-35		52-72
		Trough			
		Less severe infections	1-4		2-8
		Severe infections	4-8		8-17
		Toxic			
		Peak	>35		>72
		Trough	>10		>21

TABLE 56-2 Therapeutic and Toxic Levels of Drugs—*Continued*

Drug	Specimen	Status	Reference Interval: Conventional Units	Conversion Factor	Reference Interval: SI Units
Lamivudine (Epivir; Epivir-HBV, 3TC)	S		µg/mL	4.36	µmol/L
		Therap			
		Trough	0.1-1.0		0.5-4.4
		Peak	1.4-1.8		6.1-7.9
		Toxic	>5		>21.8
Lamotrigine (Lamictal)	S or P (Hep or EDTA)		µg/mL	3.91	µmol/L
		Therap			
		Trough	1-2		3.9-7.8
		Peak	5-8		19.6-31.3
		Toxic	>10		>39.1
Levetiracetam (Keppra)	S or P (Hep or EDTA)		µg/mL	5.88	µmol/L
		Therap			
		Trough	3-34		18-200
		Peak	10-63		59-371
		Toxic	>63		>371
Lidocaine (Xylocaine)	S or P (Hep or EDTA) ≥45 min following bolus dose		µg/mL	4.27	µmol/L
		Therap	1.5-6.0		6.4-26
		Toxic			
		CNS, cardiovascular depression	6-8		26-34
		Seizures, obtundation, decreased cardiac output	>8		>34
Lithium (Eskalith)	S or P (Hep or EDTA)		mEq/L	1.0	mmol/L
		Therap	0.6-1.2		0.6-1.2
		Toxic	>2		>2
Lorazepam (Ativan)	S or P (Hep or EDTA)		ng/mL	3.11	nmol/L
		Therap	50-240		156-746
Lysergic acid diethylamide (LSD)	P (EDTA)		ng/mL	3.09	nmol/L
		After hallucinogenic dose	5-9		15-28
	U	After hallucinogenic dose	1-50		3-155
Maprotiline (Ludiomil)	S or P (Hep or EDTA)		ng/mL	3.60	nmol/L
		Therap	200-600		720-2160
		Toxic	>600		>2160
Meperidine (Demerol)	S or P (Hep or EDTA)		µg/mL	4.04	µmol/L
		Therap	0.4-0.7		1.6-2.8
		Toxic	>1		>4.0
Mephobarbital (Mebaral)	S or P (Hep or EDTA)		µg/mL	4.06	µmol/L
		Therap	1-7		4.1-28.4
		Toxic	>15		>60.9

TABLE 56-2 Therapeutic and Toxic Levels of Drugs—*Continued*

Drug	Specimen	Status	Reference Interval: Conventional Units	Reference Interval: Conversion Factor	Reference Interval: SI Units
Meprobamate (Equanil)	S		µg/mL	4.58	µmol/L
		Therap	6-12		28-55
		Toxic	>60		>275
Methadone (Dolophine)	S or P (Hep or EDTA)		ng/mL	0.00323	µmol/L
		Therap	100-400		0.32-1.29
		Toxic	>2000		>6.46
Methamphetamine (Desoxyn)	S		µg/mL	6.70	µmol/L
		Therap	0.01-0.05		0.07-0.34
		Toxic	>0.5		>3.35
Methaqualone (Quaalude)	S or P (Hep or EDTA)		µg/mL	4.00	µmol/L
		Therap	2-3		8-12
		Toxic	>10		>40
Methotrexate	S or P (Hep or EDTA)		µmol/L	1.00	µmol/L
		Toxic			
		1-2 wk after low-dose therapy	>0.2		>0.2
		24 hr after high-dose therapy	≥5		≥5
		48 hr after high-dose therapy	≥0.5		≥0.5
		72 hr after high-dose therapy	≥0.05		≥0.05
Methsuximide (N-desmethyl methsuximide) (Celontin)	S		µg/mL	5.29	µmol/L
		Therap	0.01-0.04		0.053-0.212
		Toxic	>0.04		>0.212
Methyldopa (Aldomet)	P (EDTA)		µg/mL	4.73	µmol/L
		Therap	1-5		4.7-23.7
		Toxic	>7		>33
Methyprylon (Noludar)	S		µg/mL	5.46	µmol/L
		Therap	8-10		43-55
		Toxic	>50		273
Mexiletine (Mexitil)	S or P (Hep or EDTA)		µg/mL	4.64	µmol/L
		Therap	0.7-2.0		3.2-9.3
		Toxic	>2.0		>9.3
Morphine	S or P (Hep or EDTA)		ng/mL	3.50	nmol/L
		Therap	10-80		35-280
		Toxic	>200		>700
Mycophenolate mofetil as mycophenolic acid (CellCept)	S or P (EDTA)		µg/mL	3.12	µmol/L
		Therap	1.0-3.5		3.1-10.9
		Toxic	>12		>37.5
N-Acetylprocainamide (Pronestyl)	S or P (Hep or EDTA)		µg/mL	3.61	µmol/L
		Therap	4-30		14-108
		Toxic	>30		>108

TABLE 56-2 Therapeutic and Toxic Levels of Drugs—*Continued*

Drug	Specimen	Status	Reference Interval: Conventional Units	Conversion Factor	Reference Interval: SI Units
Nefazodone (Serzone)	S or P (Hep or EDTA)		ng/mL	2.13	μmol/L
		Therap	25-2500		53-5325
		Toxic	>2500		>5325
Nelfinavir (Viracept)	S		μg/mL	1.51	μmol/L
		Therap	1-3		1.5-4.5
		Toxic	>3		>4.5
Nevirapine (Viramune)	S		μg/mL	3.76	μmol/L
		Therap			
		Trough	3-8		11.3-30.1
		Peak	10-15		37.6-56.4
		Toxic	>15		>56.4

Zidovudine (AZT, Retrovir, azidodeoxythymidine)	S or P (Hep or EDTA)		µg/mL	3.74	µmol/L
		Therap	0.02-1.2		0.08-4.49
		Toxic	>1.2		>4.49
Zonisamide (Zonegran)			µg/mL	4.71	µmol/L
		Therap	10-30		47-141
		Toxic	>30		>141

TABLE 56-3 Critical Values

Critical values, also known as panic or alert values, are laboratory results that indicate a life-threatening situation for the patient. Because of their critical nature, urgent notification of a critical value to the appropriate healthcare professional is necessary. Table 56-3 has been adapted from extensive national surveys. The median or average critical limit determined by these surveys is shown. In practice, each organization should have its own set of critical limits and physician notification policy.

Test	Units	Lower Limit	Upper Limit	Comments
Blood Gases				
pH		7.2	7.6	Arterial, capillary
PCO_2	mm Hg	20	70	Arterial, capillary
PO_2	mm Hg	40	—	Arterial
PO_2 (children)	mm Hg	45	125	Arterial
PO_2 (newborn)	mm Hg	35	90	Arterial
Chemistry				
Albumin (children)	g/dL	1.7	6.8	Serum or plasma
Ammonia (children)	µmol/L	—	109	Plasma
Bilirubin (newborn)	mg/dL	—	15	Serum or plasma
Calcium	mg/dL	6.0	13	Serum or plasma
Calcium (children)	mg/dL	6.5	12.7	Serum or plasma
Calcium, ionized	mmol/L	0.75	1.6	Plasma
Carbon dioxide, total	mmol/L	10	40	Serum or plasma
Chloride	mmol/L	80	120	Serum or plasma
Creatinine	mg/dL	—	5.0	Serum or plasma
Creatinine (children)	mg/dL	—	3.8	Serum or plasma
Glucose	mg/dL	40	450	Serum or plasma
Glucose (children)	mg/dL	46	445	Serum or plasma
Glucose (newborn)	mg/dL	30	325	Serum or plasma
Glucose, CSF	mg/dL	40	200	CSF
Glucose, CSF (children)	mg/dL	31	—	CSF
Lactate	mmol/L	—	3.4	Plasma
Lactate (children)	mmol/L	—	4.1	Plasma
Magnesium	mg/dL	1.0	4.7	Serum or plasma
Osmolality	mOsm/kg	250	325	Serum or plasma
Phosphorus	mg/dL	1.0	8.9	Serum or plasma
Potassium	mmol/L	2.8	6.2	Serum or plasma
Potassium (newborn)	mmol/L	2.8	7.8	Serum or plasma
Protein (children)	g/dL	3.4	9.5	Serum or plasma
Protein, CSF (children)	mg/dL	—	188	CSF
Sodium	mmol/L	120	160	Serum or plasma
Urea nitrogen	mg/dL	—	80	Serum or plasma
Urea nitrogen (children)	mg/dL	—	55	Serum or plasma
Uric acid	mg/dL	—	13	Serum or plasma
Uric acid (children)	mg/dL	—	12	Serum or plasma
Hematology				
Hematocrit				
Adult	%	20	60	First report only
Newborn	%	33	71	
Hemoglobin				
Adult	g/dL	7	20	First report only
Newborn	g/dL	10	22	

Continued

TABLE 56-3 Critical Values—*Continued*

Test	Units	Lower Limit	Upper Limit	Comments
WBC				
Adult	$\times 10^3/\mu L$	2.0	30	First report only
Children	$\times 10^3/\mu L$	2.0	43	
Platelets	$\times 10^3/\mu L$	40	1000	
Blasts	Any seen (first report only)			
Drepanocytes	Presence of sickle cells or aplastic crisis			
Coagulation				
Fibrinogen	mg/dL	100	800	
Prothrombin time	s	—	30	
Partial thromboplastin time	s	—	78	
Urinalysis				
Microscopic	Presence of pathological crystals (urate, cysteine, leucine, or tyrosine)			
Chemical	Strongly positive glucose and ketones			
Cerebrospinal fluid				
WBC (0-1 yr)	Cells per μL	—	>30	
WBC (1-4 yr)	Cells per μL	—	>20	
WBC (5-17 yr)	Cells per μL	—	>10	
WBC (>17 yr)	Cells per μL	—	>5	
Malignant cells, blasts, or microorganisms		Any	Applies to other sterile body fluids

U.S. government drug detection cutoff concentrations for, 1319*t*
Capacity-limited clearance, 1246, 1246*f*
Capillary, renal, 1671, 1672, 1673*f*, 1674*f*
Capillary carbon dioxide, 2259*t*
Capillary column in gas chromatography, 150
Capillary electrophoresis, 130-135, 131*f*, 134*f*, 135*f*
for amino acids, 541
for barbiturates, 1327
in cytokine measurement, 722
in forensic DNA testing, 1544
microchip-based systems for, 250-251, 251*f*, 254, 256
microfluidic-based devices for, 247
for niacin, 1116
for polymerase chain reaction products, 1473, 1473*f*
in protein analysis, 586
Capillary gel electrophoresis, 134-135
Capillary ion electrophoresis, 124
Capillary isoelectric focusing electrophoresis, 135, 135*f*, 1173
Capillary isotachophoresis, 135
Capillary serum, 48, 48*t*
Capillary zone electrophoresis, 124, 124*f*
Capture antibody for parathyroid hormone, 1916*f*, 1916-1917
Caput medusae, 1778
Carbamate insecticides, 1288*t*, 1315*f*, 1315-1317, 1316*f*
Carbamazepine, 1249-1250, 1250*t*
analytical goals for, 365*t*
antidote for overdose, 1288*t*
effects on thyroid function, 2064*t*
therapeutic and toxic levels of, 2305*t*
Carbamoylphosphate synthetase defect, 1489-1491, 1490*f*, 2214-2215*t*, 2220-2221
Carbamylated hemoglobin, 880
Carbenicillin, 1267*t*
effects on laboratory tests, 458*t*
therapeutic and toxic levels of, 2305*t*
Carbohydrate(s), 837-901
determination of glucose in body fluids and, 868-875
glucose dehydrogenase methods in, 871
glucose oxidase methods in, 870-871
glucose reference intervals and, 871-872
hexokinase methods in, 869-870
minimally invasive monitoring of blood glucose and, 875
self-monitoring of blood glucose and, 873-875
specimen collection and storage for, 868-869
urine glucose measurement in, 872*b*, 872-873
diabetes mellitus and, 853-864
chronic complications of, 862-863
classification of, 854*b*, 854-855
diagnosis of, 859*b*, 859-861, 860*b*
gestational, 861*t*, 861-862
role of clinical laboratory in, 863*t*, 863-864
type I, 855-856
type II, 856-859
disaccharidase deficiencies and, 1862*t*, 1862-1864, 1863*b*, 1864*b*
disaccharides in, 839, 839*f*
glycated proteins measurement and, 878-886
advanced glycation end product and, 886
fructosamine and, 884-886, 885*f*
glycated hemoglobin and, 879*f*, 879*t*, 879-884, 881*t*, 883*f*
glycogen storage disease and, 890-891
glycoproteins and, 840-841, 841*f*
hypoglycemia and, 864-868, 865*b*
Carbohydrate(s) *(Continued)*
ketone bodies and, 875-877
lactate and pyruvate and, 877-878
metabolism of, 841-853
C-peptide measurement and, 853
clinical utility of measurement of hormones in, 850*b*, 850-851
counterregulatory hormones and, 849-850
digestion and absorption in, 841, 842*f*
glucagon measurement and, 853
inborn errors of, 888-890
influence of glucocorticoids on, 2007
insulin antibodies assays and, 853
insulin-like growth factors and, 849
insulin measurement and, 851-853
insulin regulation of blood glucose concentration in, 843-849, 845*f*, 846*f*, 847*t*, 848*f*
intermediary, 841, 842*f*, 843*t*
liver disease and, 1791
proinsulin measurement and, 853
somatostatin and, 850
thyroxine and, 850
monosaccharides in, 837-839, 838*f*, 839*f*
polysaccharides in, 839-840, 840*f*
urinary albumin excretion and, 886-888
Carbohydrate-deficient transferrin, 562
Carbohydrate-related tumor markers, 770*t*, 770-773
Carbon dioxide
bicarbonate-carbonic acid buffer system and, 1759-1760
critical values of, 2317*t*
gas exchange in lung and, 1763, 1764*f*
metabolic alkalosis and, 1773-1774
plasma, 2259*t*
respiratory acidosis and, 1774
respiratory alkalosis and, 1775
serum, 2259*t*
Carbon dioxide laser, 66*t*
Carbon dioxide partial pressure, 999-1014
acid-base disorders and, 1767*t*
analytical goals for, 363*t*
behavior of gases and, 999-1001, 1000*t*
calibration of, 1010-1011
continuous and noninvasive monitoring of, 1014
critical values of, 2317*t*
gas exchange in lung and, 1763, 1764*f*
Henderson-Hasselbalch equation and, 1001-1002
instrumentation for, 1008*f*, 1008-1009, 1010*f*
metabolic acidosis and, 1771
metabolic alkalosis and, 1773-1774
optical sensors for, 107, 114
oxygen in blood and, 1002-1006
hemoglobin-oxygen dissociation and, 1004-1006, 1005*f*
hemoglobin oxygen saturation and, 1003-1004
potentiometry for measurement of, 93-105
basic concepts in, 93-94, 94*f*
ion-selective electrodes in, 95-100, 96*t*, 98-100*f*
redox electrodes in, 94-95
units of measurement and, 100-101, 101*t*
quality assurance in determination of, 1011-1013
reference intervals for, 1013, 2259*t*
respiratory acidosis and, 1774, 1775
specimen acquisition for, 1006-1008, 1007*t*

Carbon dioxide partial pressure *(Continued)*
temperature correction and, 1013*t*, 1013-1014
tonometry for, 1006
Carbon furnace atomic absorption spectroscopy assay, 1136
Carbon monoxide, 1296*t*, 1296-1298
antidote for, 1288*t*
reference intervals for, 2259*t*
Carbon rod atomic absorption spectrophotometry, 74
Carbonic anhydrase inhibitors, 1771
Carboxyhemoglobin, 1167-1168
blood, 1296*t*, 1296-1297
effects of smoking on, 457
geographical influence on, 463
Carcinoembryonic antigen, 767*t*
analytical goals for, 364*t*
reference intervals for, 2259*t*
special collection and storage conditions for, 55*t*
Carcinofetal ferritin, 767*t*
Carcinogen, 746
Carcinoid syndrome, 1116
Carcinoid tumor, 1052-1054
calcitonin and, 766
chromogranins and, 777
neuron-specific enolase and, 756
Cardiac biomarkers, 1629-1660
adhesion molecules in, 1635
brain natriuretic peptide in, 1629-1631, 1631*f*, 1645-1652
biological variability of, 1650-1651, 1651*f*
implications for therapy, 1648-1649
population-based screening for, 1649-1650
use for prognosis and risk stratification, 1647-1648, 1648*t*, 1649*f*, 1650*f*
cardiac troponin I and T in, 1629, 1629*b*, 1630*f*
end-stage renal disease and, 1658, 1658*t*, 1659*f*
general clinical observations of, 1645, 1645*f*, 1646*f*
methodology for, 1635-1637, 1636*t*, 1637*b*, 1637*t*
in monitoring reperfusion following thrombolytic therapy, 1659-1660, 1660*f*
in multimarker analysis, 1660, 1660*f*
risk assessment in ischemic patient and, 1654-1657, 1656*f*, 1657*f*
role in nonischemic presentations, 1657-1658, 1658*f*
choline in, 1635
clinical utility of, 1643-1645, 1644*f*
creatine kinase isoenzymes and isoforms as, 1631-1632
acute myocardial infarction and, 1652, 1652*f*
comparison with cardiac troponins, 1640, 1640*t*
in estimation of infarct size, 1660
methodology for, 1642-1643
99th percentile reference limits for, 1639*t*
reference intervals for, 1643
cytokines in, 1633-1634
ischemia modified albumin in, 1635
isoprostanes in, 1635
lactate dehydrogenase isoenzymes in, 1632-1633, 1633*b*, 1643, 1653
matrix metalloproteinases in, 1634
monocyte chemotactic protein in, 1634
Cardiac biomarkers *(Continued)*
myeloperoxidase in, 1634
myoglobin in, 1632, 1643, 1653
nourin in, 1635
oxidized low-density lipoproteins in, 1634
phospholipase A2 in, 1634
placental growth factor in, 1634
pregnancy associated plasma protein A in, 1634
sCD40 ligand in, 1633
secreted platelet granular substances in, 1634-1635
serum amyloid in, 1633
tissue plasminogen activator antigen in, 1634
tumor necrosis factor-α in, 1634
unbound free fatty acid in, 1635
urinary thromboxane in, 1635
Cardiac conduction system, 1621-1622, 1622*f*
Cardiac cycle, 1621, 1621*f*
Cardiac disease. *See* Heart disease.
Cardiac hormones, 1024*t*
Cardiac output, renal blood flow and, 1671-1672
Cardiac risk factors, 962-968
high-sensitivity C-reactive protein in, 962-967, 963-967*f*, 966*t*
homocysteine in, 967*f*, 967-968
Cardiac troponin I and T, 1629, 1629*b*, 1630*f*, 1635-1641
end-stage renal disease and, 1658, 1658*t*, 1659*f*
general clinical observations of, 1645, 1645*f*, 1646*f*
methodology for, 1635-1637, 1636*t*, 1637*b*, 1637*t*
in monitoring reperfusion following thrombolytic therapy, 1659-1660, 1660*f*
in multimarker analysis, 1660, 1660*f*
reference intervals for, 1627*f*, 1637-1641, 1638*t*, 1639*t*
risk assessment in ischemic patient and, 1654-1657, 1656*f*, 1657*f*
role in nonischemic presentations, 1657-1658, 1658*f*
Cardioactive drugs, 1256*t*, 1256-1261
amiodarone in, 1256
digoxin in, 1256-1257, 1257*f*
disopyramide in, 1258
flecainide in, 1258
lidocaine in, 1258-1259
mexiletine in, 1259
procainamide in, 1259
propafenone in, 1259-1260
propranolol in, 1260
quinidine in, 1260
tocainide in, 1260-1261
verapamil in, 1261
Cardiolipins, 914
Cardiomyopathy, selenium-related, 1383
Cardiotoxicity of tricyclic antidepressants, 1309
Cardiovascular calcification, 1698, 1725
Cardiovascular disease
C-reactive protein and, 556, 962-967, 963-967*f*, 966*t*
chromium deficiency and, 1125
copper deficiency and, 1129
diabetes mellitus and, 1695, 1695*t*
in dialysis patient, 1723-1724, 1724*f*
selenium and, 1136
Cardizem. *See* Diltiazem.
Cardura. *See* Doxazosin.
Carnitine, 256
Carnitine acylcarnitine translocase defect, 2234-2235*t*
Carnitine palmitoyl transferase I defect, 2234-2235*t*
Carnitine palmitoyl transferase II defect, 2234-2235*t*
Carnitine uptake defect, 2234-2235*t*
Carnosinase defect, 2214-2215*t*
Carnosinemia, 2214-2215*t*
Carotenoids, 1079-1081
Carr-Price photometric method, 1083
Carrier ampholyte, 129
Carrier free radionuclide, 22
Carrier gas in gas chromatography, 149, 150-151
Carrier proteins for thyroid hormones, 2057
Carrier screening for cystic fibrosis, 1485, 1486*t*
Carryover, 272-273, 356
Carryover contamination, 1562
Cartesian systems, 283-284, 284*f*
Carumonam, 1268*t*
Caspases, 657

Diphenylcarbazone, 1294
Diphenylhydantoin, 1252
Diphosphoglycerate phosphatase, 631, 635
Diphosphoglyceromutase, 631
Diploid, term, 1514
Dipolar ion, 537
Dipstick test, 303, 809-811, 810*f*
Merckoquant sulfite, 1132-1133
for proteinuria, 576-577, 589
Direct equilibrium dialysis, 2074
Direct hemagglutination, 240
Direct ion-selective electrodes
for sodium and potassium, 986-987
for total carbon dioxide, 991
Direct methods
for free testosterone, 2130
for free thyroid hormones, 2074-2075, 2079-2081
for low-density lipoproteins, 951
for serum total protein, 587-588
for thyroid hormone-binding proteins, 2082-2083
Direct potentiometry, 100-101, 101*t*
Direct-reading potentiometer, 93-94
Direct sampling, 427-428, 428*t*
Director in molecular diagnostics laboratory, 1453
Disaccharidase deficiencies, 1862*t*, 1862-1864, 1863*b*, 1864*b*
Disaccharides, 839, 839*f*
Disc electrophoresis, 128, 129*f*
Discrepant resolution, 368
Discrete analysis, 266
Discrete dynode multiplier, 180*f*, 180-181
Discrete pipetting, 272, 272*f*
Discrimination techniques for nucleic acids, 1421-1445
closed-tube SNP genotyping methods in, 1444*f*, 1444-1445
dot-blot and line-probe assays in, 1433, 1434*f*
electrophoresis-based, 1421-1427, 1422*t*
denaturing gradient gel electrophoresis in, 1425
DNA sequencing in, 1426-1428*f*
heteroduplex migration analysis in, 1424*f*, 1424-1425
Northern blotting in, 1424
oligo ligation assay in, 1427, 1428*f*
PCR product length analysis in, 1422-1423
PCR/RFLP in, 1422, 1423*f*
single nucleotide extension assay in, 1426-1427
single-strand conformation polymorphism analysis in, 1425, 1425*f*
Southern blotting in, 1423*f*, 1423-1424
temperature-gradient electrophoresis in, 1425-1426, 1426*f*
high-performance liquid chromatography in, 1429
hybridization assays in, 1429-1433, 1430*f*
in situ hybridization in, 1434-1436
mass spectrometry in, 1429, 1430*f*
melting analysis in, 1441-1443, 1442*f*, 1443*f*
microarrays in, 1433-1434, 1434*f*, 1435*f*, 1436*t*
pyrosequencing in, 1427-1429, 1429*f*
real-time polymerase chain reaction in, 1436-1441, 1437-1441*f*, 1440*t*
Discriminatory power of identity testing, 1541
Disease
effects on thyroid hormones, 2061-2062, 2062*b*, 2062*f*
effects on vitamin and trace element status, 1077, 1077*f*
elevated sweat electrolyte concentration in, 999*b*
sequence variations in genome and, 1408-1409, 1409*f*
transmission by automated equipment, 272
tumor marker role in management of, 750-751, 751*f*
Disopyramide, 1256*t*, 1258, 1268, 2307*t*
Disseminated intravascular coagulation, 1796
Dissociated anion exchanger-based electrodes, 97
Distal renal tubular acidosis, 1707-1709
Distal tubule
anatomy and physiology of, 1675*f*, 1675-1676
water reabsorption in, 1679
Distillation, 11
Distilled water, 10
Distribution
of drug, 1244-1245
of tumor marker values, 750
Distribution of differences plot, 371-376, 372-375*f*, 373*t*, 375*t*, 376*t*
Diuretics, 1261
chloride-responsive metabolic alkalosis and, 1773
effects on laboratory tests, 458
renal disease and, 1710-1711
Dixon's range test, 437

DMD. *See* Duchenne's muscular dystrophy.

Instrument clusters, 281-282, 282*f*
Instrumentation
in atomic absorption spectrophotometry, 73*f*, 73-74, 74*f*
automated, 265-297
bar coding of specimen and, 269*f*, 269-270
chemical reaction phase and, 274-276, 275*f*, 276*f*
chemiluminescence and bioluminescence and, 278-279
development of standards for, 292
electrochemical methods and, 279
electrophoresis systems and, 124-125
evaluation of requirements for, 289-290, 290*b*
flow cytometers and, 293
fluorometry and, 278
front-surface reflectance fluorometry and, 278
hematology cell counters and, 293
historical overview of, 265-267, 268*t*
instrument clusters and, 281-282, 282*f*
labeling of specimen and, 268-269
measuring impact of, 292
microtiter plate systems and, 294
nucleic acid analyzers and, 293-294
on-analyzer specimen delivery and, 272*f*, 272-273
photometry and, 276-277, 277*f*
pipetting stations and, 294
point-of-care testing analyzers and, 294
polarization fluorometry and, 278
problems of integration in, 290-292, 291*f*
reagent delivery and, 274
reagent handling and storage and, 273-274, 274*f*
reflectance photometry and, 278
remote automated laboratory system and, 294
signal processing, data handling, and process control in, 279-280, 280*b*
specimen acquisition and, 268
specimen delivery to laboratory and, 270-271
specimen loading and aspiration and, 271-272
specimen preparation and, 271
specimen processing and, 284-288, 285*f*, 287*f*
specimen sorting and, 288*f*, 288-289, 289*f*
specimen storage and retrieval and, 289
specimen transport and, 282-284, 284*f*
turbidimetry and nephelometry and, 278
urine analyzers and, 292
workcells and, 282, 282*f*
workstations and, 281
blood gas, 1008*f*, 1008-1009, 1010*f*
in capillary electrophoresis, 131*f*, 131-133
Instrumentation *(Continued)*
in chemiluminescence, bioluminescence, and electrochemiluminescence, 85, 278-279
in conventional electrophoresis, 122-125, 123*f*
in fluorometry, 77*f*, 77-83
automated, 278
cuvets and, 78-79, 79*f*
excitation and emission monochromator and, 78
excitation source for, 77-78
flow cytometer and, 82-83, 83*f*
hematofluorometer and, 83
performance verification and, 80
photodetector and, 79-80
ratio-referencing spectrofluorometer and, 8-81, 81*f*
time-resolved fluorometer and, 81-82
in forensic DNA testing, 1544
in gas chromatography, 149-155
carrier gas supply and flow control in, 150-151
column technology and, 149-150, 150*t*
computer in, 154-155, 155*f*
detectors in, 153*t*, 153-154, 154*f*
injector in, 151, 151*f*, 152*f*
sample extraction and, 155
temperature control and, 151-153
in liquid chromatography, 155-160, 156*t*, 157-159*f*, 159*t*
in mass spectrometry, 167-181
beam-type mass spectrometer in, 172-174*f*, 172-176
computer and software in, 181
detectors in, 180*f*, 180-181
ion source and, 167*f*, 167-171, 169*f*, 170*f*
tandem mass spectrometer in, 179-180
trapping-mass spectrometer in, 176-179, 177*f*
vacuum system in, 171
in microchip electrophoresis, 135-136, 136*f*
in nephelometry and turbidimetry, 88, 88*f*, 278
in parentage testing, 1551
selection of method and, 355
in spectrophotometry, 64*f*, 64-72, 65*f*
cuvets and, 69
fiber optics and, 68-69
light sources for, 65-66, 66*t*
linearity and, 72
microprocessor and, 70
multiple-wavelength readings and, 72
photodetectors and, 69*f*, 69-70
photometric accuracy and, 72, 72*t*
readout device and, 70
recorder and, 70
spectral bandwidth and, 71
spectral isolation and, 66-68, 67*f*, 68*f*
stray light and, 71-72
wavelength calibration and, 70-71, 71*f*
Insulin, 843-849, 1019, 1023*t*
C-peptide and, 846, 851
chemistry of, 843
chromium and, 1378
circadian variation in, 452
degradation of, 846
effects of exercise on, 451
fasting and starvation and, 456
glucose transport and, 847*t*, 847-849
growth hormone and, 1971, 1973*f*, 1974*b*
hypophosphatemia and, 1906

Insulin *(Continued)*
measurement of, 851-853
clinical utility of, 850, 850*b*
for hypoglycemia, 865
mechanism of action, 847, 848*f*
morphine and, 459
obesity and, 465
reference intervals for, 2280*t*
release of, 844-846, 846*f*
smoking and, 457
special collection and storage conditions for, 55*t*
synthesis of, 843-844, 845*f*, 846*f*
therapy in diabetic nephropathy, 1701
Insulin antibodies, 846-847, 852
assay of, 853
hypoglycemia and, 866
in type 1 diabetes mellitus, 856
Insulin-dependent diabetes mellitus, 854
Insulin-induced hypoglycemia stimulation test, 1989, 2018
Insulin-like growth factor(s), 849, 1969-1976, 1971
Insulin-like growth factor binding protein, 1971
Insulin-like growth factor-I, 849, 2280*t*
Insulin-like growth factor-I receptor, 849
Insulin-like growth factor-II, 849, 1024*t*

Insulin-receptor substrate proteins, 847
Insulin-related subfamily of cytokines, 648
Insulin resistance, 857
Insulin resistance gene, 858
Insulin secretion gene, 858
Insulin tolerance test, 1974*b*, 1989
Insulinoma-associated antigen, 856
Insulinopenia, 854
Insulitis, 855
Integrated automation system for specimen processing, 286-288, 287*f*
Inter-α-trypsin inhibitor, 564*t*
Interface to automated analyzer, 286
Interference, 361-362
in atomic absorption spectrophotometry, 74-75
in blood estrogen measurement, 2135
in free calcium measurement, 1900
in immunoassay, 239
mean bias and random bias and, 369-370
in measuring high-density lipoproteins, 948
in phosphate measurement, 1908
in thyroglobulin determination, 2084
in total calcium measurement, 1899, 1899*b*
Interference filter of spectrophotometer, 67
Interferon(s), 653, 695
Interferon-α, 653, 696*f*, 696-698
Interferon-β, 696*f*, 696-698
Interferon-γ, 698-702, 699*f*, 701*t*
interleukin-12 and, 683, 685
interleukin-15 and, 689
interleukin-17 and, 694
interleukin-18 and, 695
natural killer cell and, 650-651, 651*f*
neurological disorders and, 708
tumor necrosis factor-α and, 704-706
Interferon-α receptor, 696-697
Interferon-β receptor, 696-697
Interferon-γ receptor, 699
Interleukin-1, 648-649, 655-660
alpha$_2$-macroglobulin and, 554
biological actions of, 658-659, 659*t*
clinical significance of, 659-660
Interleukin-1 *(Continued)*
control of synthesis and release of, 656-657, 657*b*
general characteristics of, 655-656, 656*f*
interferon-γ and, 699
in interleukin-6 secretion, 672
in synthesis of interleukin-11, 681
therapeutic applications of, 660
Interleukin-1α, 655-656
Interleukin-1β
myocardial contractility and, 652
tuberculosis and, 660
Interleukin-1 converting enzyme, 656
Interleukin-1 receptor, 657*f*, 657-658
Interleukin-1 receptor antagonist, 655, 658
Interleukin-2, 660-664, 661*f*, 663*b*
in immune response to tumor, 654, 654*f*
interferon-γ and, 699
interleukin-15 and, 690-691
Interleukin-2 receptor, 661-662
Interleukin-3, 664-666, 665*f*
Interleukin-3 receptor, 665
Interleukin-4, 666-669, 667*f*, 687
Interleukin-4 receptor, 667
Interleukin-5, 669-671, 670*f*, 690
Interleukin-5 receptor, 670
Interleukin-6, 671-675, 672*f*, 673*t*
cancer and, 653
in diagnosis of myeloma, 655
interleukin-10 inhibition of, 678, 682-683
neuropathies and, 707-708
as potential uremic toxin, 1692*t*
Interleukin-6 receptor, 672-673
Interleukin-7, 675*f*, 675-676
Interleukin-7 receptor, 676
Interleukin-8, 676
Interleukin-9, 676-678, 677*f*
Interleukin-9 receptor, 677
Interleukin-10, 678*f*, 678-680, 679*b*
in inhibition of interleukin-12, 682-683
neuropathies and, 707-708
Interleukin-10 receptor, 679
Interleukin-11, 680-682, 681*f*
Interleukin-11 receptor, 681
Interleukin-12, 682-686, 683*f*
interferon-γ and, 699
interleukin-10 effects on, 678
Interleukin-12 receptor, 683
Interleukin-13, 686*f*, 686-688
Interleukin-13 receptor, 687
Interleukin-14, 688*f*, 688-689
Interleukin-14 receptor, 688
Interleukin-15, 689*f*, 689-691
Interleukin-15 receptor, 689-690
Interleukin-16, 691*f*, 691-693
Interleukin-16 receptor, 692
Interleukin-17, 693-694, 694*f*
Interleukin-17 receptor, 694
Interleukin-18, 694-695, 695*f*
Intermediary metabolism of carbohydrates, 841, 842*f*, 843*t*
Intermediate cluster region, 1464
Intermediate-density lipoproteins, 915
characteristics of, 916*t*
chemical composition of, 916*t*
familial combined hyperlipidemia and, 929-930
measurement of, 953
reverse cholesterol transport pathway and, 921*f*
Intermediate precision, 356*t*, 357
Internal calibrator, 1558
Internal controls in molecular assay, 1557
Internal quality control, 515
Internal standardization of analytes, 161-162
Internal validity, 328-329
International Federation of Clinical Chemistry/International Union of Pure and Applied Chemistry system, 9-10, 10*t*

Metal toxicity *(Continued)*
antimony in, 1375-1376
arsenic in, 1376*f*, 1376-1377
beryllium in, 1377
cadmium in, 1377-1378
chromium in, 1378
classification of, 1372-1373, 1373*f*
cobalt in, 1378
copper in, 1378-1379
diagnosis of toxicity, 1372, 1372*t*
iron in, 1314-1315, 1379
lead in, 1379*f*, 1379-1381, 1380*f*
manganese in, 1381
mercury in, 1381-1382, 1383*f*
nickel in, 1383
occupational monitoring of, 1372
platinum in, 1383
prevalence of, 1371-1372
selenium in, 1383-1384
silicon in, 1384
silver in, 1384
thallium in, 1384
Metallothionein, 1139, 1141
Metanephrines
adrenal medullary system and, 1044*t*
drug-induced increases in, 1056*t*
pheochromocytoma and, 1047-1048
plasma, 1057-1058, 1058*t*
reference intervals for, 2284*t*, 2285*t*
urine, 1060-1061, 1061*t*
urine specimen preservatives and, 51*t*
Metaproterenol, 1261
Metastasis
chemokines and, 716-717
cytokines and, 653-654
interleukin-10 and, 680
markers of angiogenesis and, 786
neuroblastoma and, 1049
pheochromocytoma and, 1046
Metenkephalin, 1021*t*, 1981, 1984
Methadone, 1345-1346, 1346*f*
chemical structure of, 1340*f*
effects on thyroid function, 2064*t*
therapeutic and toxic levels of, 2310*t*
Methamphetamine, 1320-1322, 1322*f*, 1324-1325
chemical structure of, 1321*f*
SAMSHA guidelines for drug assay cutoff values, 1320*t*
therapeutic and toxic levels of, 2310*t*
U.S. government drug detection cutoff concentrations for, 1319*t*
Methanol, 1301-1302
antidote for overdose, 1288*t*
metabolic acidosis and, 1769
reference intervals for, 2285-2286*t*
serum osmolality of, 1293*t*
Methaqualone, 2310*t*
Methemalbuminemia, 560
Metheme, 559
Methemoglobin, 633, 1168, 2286*t*
Methemoglobin-forming agents, 1298-1300, 1299*f*, 1299*t*
Methemoglobinemia, 1168, 1298-1299, 1299*f*, 1299*t*
Methicillin, 1267*t*
Methionine
conversion to homocysteine and cysteine, 967, 967*f*, 2219*f*
metabolism of, 1112, 1112*f*
reference intervals for, 2286*t*
structure and molecular weight of, 534*t*
Methionine adenosyltransferase defect, 2212-2213*t*
Method comparison and evaluation, 353-407
analytical measurement range and, 359
analytical performance criteria and, 354
analytical sensitivity and, 361
analytical specificity and interference in, 361-362
basic error model in, 368-370, 369*f*
Bland-Altman plot and, 376-377, 377*f*, 377*t*
calibration and, 355*f*, 355*t*, 355-356
distribution of differences plot in, 371-376, 372-375*f*, 373*t*, 375*t*
goals for analytical quality in, 362*f*, 362-366*t*, 362-368
guidelines, regulatory demands, and accreditation in, 402-403
identifying sources of analytical errors and, 520
limit of detection and, 359-361, 360*f*, 361*f*
limit of quantification and, 361
linearity in, 359
medical criteria in, 353-354, 354*f*
method comparison data model in, 370-371
monitoring serial results in, 396-397, 397*f*
paired *t*-tests and, 377-378, 378*f*, 378*t*
precision in, 357-358, 358*t*
precision profile in, 358, 358*f*
regression analysis and, 378-395
adjustments for recalibration in, 387*f*, 387-388, 388*f*
application of, 389-390, 390*f*, 390*t*
assessment of outliers in, 383, 384*f*
correlation coefficient in, 383-385, 384*f*
Deming ordinary least-squares, 379-381*f*, 379-382
error models in, 378-379, 379*f*
estimating sample size for method comparison studies in, 390-395, 391*f*, 392*f*, 392*t*, 393*t*
interpretation of systematic differences between methods in, 389
nonparametric, 388-389
proportional random errors and, 385*f*, 385-386, 386*f*, 395, 395*t*
random error around estimated regression line in, 382-383, 383*f*
random errors in both *x*1 and *x*2 measurements and, 386-387, 387*f*, 395
random errors in *x*2 measurements and, 386
testing for linearity in, 388, 388*f*
software packages for, 403-404
traceability and measurement uncertainty in, 397-402, 398*f*, 401*t*
trueness and accuracy in, 356, 356*t*
verification of distribution of differences in relation to specified limits in, 376, 376*t*
Methods. *See* Analytical methods.
Methotrexate, 1272-1273, 1273*t*
development of nephropathy and, 1708*t*
male reproductive function and, 2122*t*
therapeutic and toxic levels of, 2310*t*
3-Methoxy-4-hydroxyphenylglycol, 1038, 1038*f*
Methsuximide, 1250*t*, 1255, 2310*t*

Serum citric acid, 55*t*
Serum cobalt, 2262*t*
Serum complement, 55*t*
Serum complement C3, 2262*t*
Serum complement C4, 2262*t*
Serum conjugated bilirubin, 2258*t*
Serum copper, 2262*t*
Serum cortisol, 2016, 2039
in adrenocortical insufficiency, 2022, 2023*f*, 2023*t*
reference intervals for, 2263*t*
shock-related changes in, 466
travel-related changes in, 453
Serum creatine, 456
Serum creatine kinase, 2263*t*
drug-related effects on, 458*t*
influence of menstrual cycle on, 464
Serum creatine kinase isoenzymes, 55*t*, 2263*t*
Serum creatine kinase isoforms, 2263*t*
Serum creatinine
childhood levels of, 461
circadian variation in, 453*t*
effect of exercise on, 452*t*
effect of fever on, 466*t*
fasting and starvation and, 456
influence of age on, 460*t*
influence of gender on, 462*t*
influence of menstrual cycle on, 464
reference intervals for, 2264*t*
seasonal influences on, 464*t*
smoking and, 457
special collection and storage conditions for, 55*t*
Serum cryoglobulins, 55*t*
Serum cystine, 2264*t*
Serum dehydroepiandrosterone, 2133, 2133*t*, 2265*t*
Serum dehydroepiandrosterone sulfate, 2133, 2133*t*, 2266*t*
Serum 11-deoxycortisol, 2266*t*
Serum digitoxin, 55*t*
Serum digoxin, 55*t*
Serum dihydrotestosterone, 2266*t*
Serum enzymes
adult levels of, 461
alcohol ingestion and, 458
surgery-related changes in, 466
Serum estradiol, 2267-2268*t*
Serum estriol, 2107
Serum estrone, 2268-2269*t*
Serum ethanol, 1303
Serum ethylene glycol, 1314
Serum ferritin, 1191, 1191*t*, 2269*t*
Serum fluoride, 55*t*, 2270*t*
Serum folate, 2270*t*
Serum follicle-stimulating hormone, 2270*t*
Serum free calcium, 2258*t*
Serum free estriol, 2268*t*
Serum free testosterone, 2118, 2295*t*
Serum free thyroxine index, 2298*t*
Serum free triiodothyronine, 2300*t*
Serum fructosamine, 2270*t*
Serum gamma-glutamyltransferase, 2271*t*

Serum gastrin, 55*t*
Serum glucose
  food ingestion and, 454
  influence of age on, 460*t*
  influence of food on, 455*t*
  influence of gender on, 462*t*
  reference intervals for, 871, 2270-2271*t*
  smoking and, 457*t*
  travel-related changes in, 453
Serum growth hormone, 454, 1975, 2272*t*
Serum haptoglobin, 2272*t*
Serum high-density lipoproteins, 2274*t*
Serum histidine, 55*t*
Serum homocysteine, 2274-2275*t*
Serum 17-hydroxyprogesterone, 55*t*, 2041-2042
Serum immunoglobulin A
  anticonvulsants and, 459
  effects of smoking on, 457
  in elderly, 461
  posture-related changes in, 450*t*
  reference intervals for, 2279*t*
Serum immunoglobulin D, 2279*t*
Serum immunoglobulin E, 2279*t*
Serum immunoglobulin G
  anticonvulsants and, 459
  childhood levels of, 461
  effects of smoking on, 457
  in elderly, 461
  posture-related changes in, 450*t*
  reference intervals for, 2279*t*
Serum immunoglobulin M
  effects of smoking on, 457
  in elderly, 461
  posture-related changes in, 450*t*
  reference intervals for, 2279*t*
Serum inhibin-A, 2279-2280*t*
Serum insulin, 55*t*, 2280*t*
Serum insulin-like growth factor-I, 2280*t*
Serum iron, 1188-1191, 1189*t*, 1190*t*
  circadian variation in, 453*t*
  food ingestion and, 454
  malnutrition and, 456
  transfusion-related changes in, 467
Serum isocitrate dehydrogenase, 55*t*
Serum lactate dehydrogenase, 602
  circadian variation in, 453*t*
  diet and, 453
  fasting and starvation and, 456
  influence of food on, 455*t*
  reference intervals for, 2282*t*
  seasonal influences on, 464*t*
  transfusion-related changes in, 467
Serum lipase, 2282*t*
Serum lipoproteins
  reference intervals for, 2274*t*, 2282-2283*t*
  special collection and storage conditions for, 55*t*
Serum low-density lipoproteins, 2282-2283*t*
Serum lysozyme, 55*t*
Serum magnesium, 1911, 1912
  effect of fever on, 466*t*
  fasting and starvation and, 456
  reference intervals for, 2284*t*
  special collection and storage conditions for, 55*t*
Serum manganese, 1132, 2284*t*
Serum metanephrine, 2284*t*, 2285*t*
Serum methylmalonic acid, 1104
Serum molybdenum, 2287*t*
Serum mucinlike carcinoma-associated antigen, 2287*t*
Serum nickel, 2287*t*
Serum normetanephrine, 2284*t*
Serum 5'-nucleotidase, 612
Serum osmol gap, 1292-1293, 1293*t*
Serum osteocalcin, 2288*t*
Serum parathyroid hormone, 55*t*, 1917-1918, 2289*t*
Serum pepsinogen, 55*t*
Serum phosphatase, 2290*t*
Serum phosphate, 1908, 1908*f*
  circadian variation in, 453*t*
  effect of exercise on, 452*t*
  effect of fever on, 466*t*
  fasting and starvation and, 456
  in hyperphosphatemia, 1907
  in hypophosphatemia, 1905-1906
  influence of food on, 455*t*
  influence of gender on, 462*t*
  influence of menstrual cycle on, 464
  reference intervals for, 2290*t*
Serum phospholipids, 457*t*
Serum phosphorus
  food ingestion and, 454
  influence of age on, 460*t*
Serum placental lactogen, 55*t*
Serum potassium
  circadian variation in, 453*t*
  effect of fever on, 466*t*
  in hyperaldosteronism, 2030*f*
  influence of food on, 455*t*
  reference intervals for, 2291*t*
  transfusion-related changes in, 467
Serum progesterone
  for evaluation of ovulation, 2125-2126
  reference intervals for, 2291*t*
  threatened abortion and, 2162
Serum proinsulin, 2291*t*
Serum prolactin, 55*t*, 2291-2292*t*
Serum prostaglandin $F_2\alpha$, 55*t*
Serum prostate-specific antigen, 2292*t*
Serum protein(s)
  reference intervals for, 2292-2293*t*
  stain in conventional electrophoresis, 125*t*
Serum protein electrophoresis, 584-586, 585*f*
Serum retinol binding protein, 2293*t*
Serum reverse triiodothyronine, 2293*t*
Serum riboflavin, 1097, 2293*t*
Serum salicylate, 1307-1308
Serum selenium, 2294*t*
Serum serine, 2294*t*
Serum serotonin, 2294*t*
Serum sodium, 47*t*
  circadian variation in, 453*t*
  effect of fever on, 466*t*
  influence of food on, 455*t*
Serum N-telopeptide, 2287*t*
Serum testosterone, 2127-2129, 2129*t*
  in male infertility, 2122-2123
  reference intervals for, 2131*t*, 2295*t*
Serum thiamine, 1093
Serum thiocyanate, 2297*t*
Serum thyroglobulin, 2297*t*
Serum thyroid-stimulating hormone, 2063-2064, 2066, 2297*t*
  circadian variation in, 452
  hypothyroidism *versus* euthyroid sick syndrome and, 2062-2063
Serum thyrotropin, 2297*t*
Serum thyroxine, 2068-2071
  circadian variation in, 452
  neonatal, 460
  posture-related changes in, 450*t*
  reference intervals for, 2298*t*
Serum thyroxine-binding globulin, 2080-2081, 2298*t*
Serum total bilirubin, 2258*t*
Serum total calcium, 2258*t*
Serum total carbon dioxide, 991
Serum total cortisol, 2263*t*
Serum total estriol, 2268*t*
Serum total protein, 586-589
Serum total testosterone, 2118, 2295-2296*t*
Serum total triiodothyronine, 2300*t*
Serum transferrin
  influence of altitude on, 463
  reference intervals for, 2299*t*
  transfusion-related changes in, 467
Serum transferrin receptor, 1191-1192
Serum transthyretin, 2299*t*
Serum triglycerides
  adult levels of, 461
  alcohol ingestion and, 458
  diet and, 453
  effects of exercise on, 451
  malnutrition and, 455
  obesity and, 464-465
  posture-related changes in, 450*t*
  racial differences in, 463
  reference intervals for, 2299*t*
  seasonal influences on, 463, 464*t*
  smoking and, 457, 457*t*
  travel-related changes in, 453
Serum triiodothyronine, 2061, 2071-2073
Serum tube additives, 44*t*, 45
Serum tumor-associated trypsin inhibitor, 2300*t*
Serum urate
  adult levels of, 461
  diet and, 453
  effects of exercise on, 451
  fasting and starvation and, 456
  food ingestion and, 454
  seasonal influences on, 463
Serum urea nitrogen
  circadian variation in, 453*t*
  effect of exercise on, 452*t*
  effect of fever on, 466*t*
  food ingestion and, 454
  influence of age on, 460*t*
  influence of food on, 455*t*
  influence of gender on, 462*t*
  malnutrition and, 456
  reference intervals for, 2301*t*
  seasonal influences on, 464*t*
  smoking and, 457, 457*t*
Serum uric acid, 2301*t*
  circadian variation in, 453*t*
  effect of exercise on, 452*t*
  effect of fever on, 466*t*
  influence of age on, 460*t*
  influence of food on, 455*t*
  influence of gender on, 462*t*
  seasonal influences on, 464*t*
Serum vitamin A, 1084
  reference intervals for, 2302*t*
  special collection and storage conditions for, 55*t*
Serum vitamin B_{12}, 2302*t*
Serum vitamin C, 2302*t*
Serum vitamin E, 1087, 2302*t*
Serum vitamin K, 2302*t*
Serum zinc, 55*t*, 2302*t*
Serzone. *See* Nefazodone.
Seventy-two hour fast, 865-866
Severe combined immunodeficiency, 633
Severinghaus style electrode for PCO_2, 99, 99*f*

Sex
as noncontrollable preanalytical variable, 462*t*, 463
in partitioning of reference group, 430, 431*b*
reference intervals for catecholamines and, 1056
Sex hormone-binding globulin, 2011-2012
estrogens and, 2105
levels during pregnancy, 2157
testosterone and, 2099, 2129
Shared receptors, 718
Sharp-cutoff filter in spectrophotometry, 67, 67*f*
SHBG. *See* Sex hormone-binding globulin.

APPENDIX 1

Introduction to Principles of Laboratory Analyses and Safety

Edward W. Bermes, Jr., Ph.D., Stephen E. Kahn, Ph.D., and Donald S. Young, M.B., Ph.D.

CHEMICALS, REFERENCE MATERIALS, AND RELATED SUBSTANCES

Specific Systems for the Preparation of Reagent Grade Water

Any system may be used as long as the desired specifications are attained. Considerations in the selection of a system to produce type 1 reagent grade water might include quality of feed water, amount of water needed, availability of space near the area of use, and electrical energy cost in the area. In general, if the feed water contains more than 1000 ppm of total dissolved solids (TDS), reverse osmosis should be considered as a pretreatment option.

Type 1 reagent water, with a neutral pH and 170 ppm of TDS, can be produced from municipal feed water by use of a primary dual filtration cartridge to remove particulate matter and organics, followed by two tanks containing a mixed-bed ion-exchange resin. The tanks are followed by a 0.2-μm membrane filter. A conductivity light installed between the two ion-exchange tanks is automatically turned off when the resistance of the effluent from the first tank goes below 200,000 ohm/cm. The second tank then "polishes" the water to yield water with a resistance of up to 15 Mohm/cm. When the deionizers are exchanged, the first tank is removed for regeneration, the second tank is put in its place, and the new tank is put in the second position. The spigot for water delivery should be within a few feet of the final filter.

Purity of Organic Reagents

The purity of commercially obtained organic reagents for clinical chemistry purposes is generally inferior to that of inorganic reagents. Most of the impurities in these compounds have been introduced in their synthesis, either along with the starting materials or as byproducts; such impurities are presumably more difficult or more expensive to remove than are impurities in inorganic substances. In addition, some organic compounds oxidize or decompose on standing, and the amount of impurities from this cause depends on how long the bottle of reagent has been opened or stored and under what conditions. Stability is often improved when the compounds are stored in amber bottles and refrigerated; however, phenols and amines oxidize on standing and tend to darken even when refrigerated. Sugars are quite hygroscopic and absorb moisture rapidly unless they are stored in a desiccator.

The presence of impurities in an organic reagent may be a source of difficulty in its use. If the contaminant does not react with the substance being determined, no interference will occur as long as there are no interfering side reactions and there is enough of the original reactant remaining. If a reagent is impure, the net final color developed in a photometric reaction may be considerably more than desirable because of a high blank caused by the impurity. The existence of isomers and their presence in a particular lot of an organic reagent may be a cause of analytical problems, because in the rather specific geometrical requirements of a chelate ring, only certain isomers may produce the desired colored complex; or in enzyme reactions, only one of the isomers may be suitable as substrate.

Organic solvents are available in several grades of purity. The common grades are listed in Table A1-1. The degree of purity required for the solvent depends on the application. The details of purification procedures are included in most comprehensive analytical chemistry texts. Because of the variety of grades available, it is rarely necessary to redistill reagents in the clinical laboratory.

The properties of some of the organic solvents commonly used in the clinical laboratory are listed in Table A1-2.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

TABLE A1-1 Common Grades of Organic Solvents

Practical Grade	Contains some impurities but usually adequate for most organic preparations
USP Grade and NF Grade	Meets standards established by the U.S. Pharmacopeia (USP) or National Formulary (NF); may contain impurities that have not been tested for
Chemically Pure (CP)	Almost as pure as reagent grade chemicals
Spectroscopic Grade	Spectrally pure in the visible, ultraviolet, and near- and mid-infrared ranges
Chromatographic Grade	Minimum purity of greater than 99% as determined by gas chromatography; no single impurity exceeding 0.2%
Reagent Grade	Certified to contain impurities below levels established by the Committee on Analytical Reagents of the American Chemical Society

Organic solvents in general should be considered potentially hazardous to health, and thus inhalation of fumes should be avoided. Unless a solvent is known to be nonflammable, it should be considered a potential fire hazard. Diethyl ether has a particularly high flammability rating. Proper storage conditions are essential to minimize the dangers of organic solvents. Pure solvents are best stored in glass containers under an inert gas either in a sealed container or under positive pressure. With some solvents, sealing the stopper with paraffin wax prolongs storage life. The maximum quantities of solvents that can be stored in particular types and sizes of containers are described by Occupational Safety and Health Administration (OSHA) regulations (see section on safety).

Desiccants and Use of Desiccators

In the clinical laboratory it is often necessary to dry a chemical before it can be used. Various techniques are used to dry a chemical, including placing it into a drying oven or desiccator for a specific period of time. Various desiccants are used and every effort should be made to avoid those that produce dust when used in desiccators. Granular calcium chloride, for example, frequently carries a large amount of dusty "fines" when fresh. Drying agents that incorporate cobalt chloride or some other moisture-sensitive salt to indicate an exhaustion are much preferred to those that do not contain such indicators. Silica gel and anhydrous calcium sulfate (Drierite) are sold with indicators included. Although expensive, such forms are frequently worth their high cost.

Desiccators should be opened carefully. Ordinary desiccators often contain air at less than atmospheric pressure as a result of cooling the warm air formed from hot samples added before closure. If such a desiccator is not opened slowly, the inrush of air may create drafts sufficient to dislodge materials from open vessels or to stir up dust particles from the drying agent that may subsequently settle in the vessels that are being stored. Vacuum desiccators should be provided with a curved inlet tube to deflect incoming air against the lid, and the stopcocks on these should be opened very carefully when restoring the internal pressure to that of the atmosphere.

The properties of various desiccants are described in Table A1-3; two of these are distinctly alkaline, and one is strongly acidic. The choice of the drying agent required for the quantitative absorption of moisture depends not only on the composition of the gases or materials to be dried, but also on convenience, efficiency, and sometimes cost. For example, magnesium perchlorate quantitatively absorbs ammonia gas, and anhydrous calcium chloride (technical grade) absorbs carbon dioxide and ammonia. These facts should be kept in mind when choosing a desiccant intended for the quantitative removal of water from gases, which may also contain ammonia, carbon dioxide, or other reactive substances. Certain drying reagents are deliquescent, and, when liquefaction of the drying agent occurs, a decline in drying efficiency results. Calcium chloride and magnesium perchlorate are examples; however, both have a considerable capacity before deliquescence sets in. Phosphorus pentoxide is one of the most powerful drying agents in use, but its effective capacity is rapidly reduced by formation of metaphosphoric acid on uptake of water.

Some drying agents can easily be regenerated, and this is an important consideration when comparing costs. Silica gel can be regenerated by heating in a drying oven at 120 °C, whereas anhydrous calcium sulfate and activated alumina require temperatures of 275 °C and 175 °C, respectively. Magnesium perchlorate can be regenerated by heating to 240 °C in a partial vacuum.

GENERAL LABORATORY SUPPLIES

Most of the laboratory ware used in the clinical laboratory today is made of either glass or plastic, both of which may be of several different types. Thus an item such as a beaker may be made from a variety of different materials. The properties of these materials may permit or restrain the types of analyses performed in containers or devices composed of them.

Glassware

Glass is a complex silicate, the properties of which depend on the type of silicate anion in the structure as well as its

TABLE A1-2 Properties of Some Organic Solvents Used in the Clinical Laboratory

	Boiling Point (°C)	Flash Point (°C)	Specific Gravity	TLV	Characteristics
Acetone	56	−20	0.79	750	Clear, colorless, volatile liquid, very soluble in water; vapors heavier than air; vapor-air mixtures are explosive
1,2-Dichloroethane	84	13	124	10	Clear, colorless liquid, negligible solubility in water; dangerous when exposed to flame
Diethyl ether	34.5	−45	0.71	400	Colorless, mobile, extremely volatile liquid, 8.4% soluble in water at 15 °C; very flammable and reactive; reacts with many inorganic compounds and acids; potentially extremely dangerous fire and explosion hazard
Ethyl acetate	77.1	−4.4	0.90	400	Colorless liquid, solubility 8.7 g/100 g water at 20 °C; contact with nitrates, strong oxidizers, strong alkalis, or strong acids may cause fire and explosions
n-Hexane	69	−22	0.65	50	Clear, colorless solution, insoluble in water; extremely flammable; contact with oxidizing materials may cause extremely violent combustion; incompatible with strong oxidizers
Isobutyl alcohol	108	28	0.80	50	Colorless, volatile liquid, 8.5% soluble in water; vapors heavier than air; fire hazard when exposed to heat, flame, or oxidizers
Isopropyl alcohol	82	12	0.79	400	Clear, colorless liquid, completely soluble in water; above flash point, vapor-air mixtures are explosive; contact with strong oxidizers may cause fire or explosion
Methyl alcohol	65	11	0.79	200	Clear, colorless liquid, very soluble in water; vapors are heavier than air; vapor-air mixtures are explosive; may form explosive mixture or cause violent reaction with many organic or inorganic compounds
Toluene	111	4	0.87	50	Clear, colorless liquid, 0.05% soluble in water; soluble in many organic solvents; dangerous fire hazard when exposed to heat or flame; vapor-air mixtures are explosive
Xylene	138-144	27-32	0.86	100	Light-colored or colorless mobile liquid; solvent in many organic compounds; dangerous fire hazard when exposed to heat or flame; vapors heavier than air

Data compiled from Lide DR ed. CRC Handbook of chemistry and physics, 84th ed. Boca Raton, FL, CRC Press. 2003-2004: 15.14-18.
TLV, Threshold limit for allowable airborne concentration, given in parts per million by volume at 25 °C and atmospheric pressure.

cation content. The addition of metal cations, such as Fe^{3+} or Ni^{2+}, to the basic structure of glass can alter its color.

Type of Glass

The thermal properties of glass can be significantly changed by the addition of boron oxide (B_2O_3). Glassware containing boron oxide, known as *borosilicate glass,* is extensively used in clinical laboratories.

Glass with high thermal resistance is usually a borosilicate glass that has a low alkali content. It is free from zinc group elements and heavy metals (arsenic and antimony), and resists heat, corrosion, and thermal shock. Because its dimensions change very little with temperature (it has a relatively low coefficient of expansion), this type of glassware should be used whenever heating or sterilization by heat is to be carried out. Some borosilicate glassware, if properly

TABLE A1-4 Thermal Durability of Borosilicate Glass

Strain point*	510 °C
Annealing point†	555 °C
Softening point	820 °C

*Temperature at which deformation may result because of heat stress.
†Temperature to which glass must be heated to relieve strains.

supported and not under internal pressures, can be heated to about 600 °C for a relatively short period of time. If the glass is cooled too quickly, however, it will acquire strains that may affect its future serviceability. The highest safe operating temperature of this glass is its *strain point.* The thermal durability of borosilicate glass is shown in Table A1-4.

Pyrex (Corning) and *Kimax* (Kimble) brand glass products are the most common thermal-resistant borosilicate glassware found in the laboratory. Most clinical laboratory apparatus—such as beakers, flasks, and pipettes—are made of this type of glass. Because the vessel contains so few elements, it contaminates liquids minimally, even when they are hot.

In 1965 a special alumina-silicate glass was developed that was at least six times stronger than borosilicate glass. This *Corex* (Corning) brand laboratory glassware has been strengthened chemically rather than thermally. Corex pipettes have a typical impact strength of 206.845 $MN \cdot m^{-2}$ compared with a rating of 13.790 $MN \cdot m^{-2}$ to 34.475 $MN \cdot m^{-2}$ for borosilicate pipettes. Corex laboratory glassware is harder than conventional borosilicates and better able to resist clouding due to alkali and scratching. This glass is also used for higher-temperature thermometers (>250 °C), graduated cylinders, and centrifuge tubes.

Vycor (Corning) brand laboratory glassware is recommended for use in applications involving high temperatures, drastic heat shock, and extreme chemical treatment with acids and dilute alkalis. This transparent glassware is resistant to attack by all acids, except hydrofluoric, and even in the upper temperature range it is more resistant to alkali than is borosilicate glass. Vycor ware is used primarily in ashing and ignition techniques. It can be heated to 900 °C and can withstand the shock of a temperature drop from 900 °C to 0 °C.

The high silica content of *high-silica glass* (more than 96%) makes it comparable with fused quartz in its thermal endurance, chemical stability, and electrical characteristics. The glass is made by removing almost all elements except silica from borosilicate glass. It is radiation resistant and has good optical qualities and temperature characteristics; it is used for high-precision analytical work and can also be used for optical reflectors and mirrors.

Boron-free glassware has high resistance to alkali and was developed particularly for use with strongly alkaline solutions. Its thermal resistance is much less than that of borosilicate glass, and it must therefore be heated and cooled very carefully. Its primary use should be with solutions or for digestion involving strong alkali. This glass is often referred to as *soft glass.*

Low actinic glassware contains materials that usually impart an amber or red color to the glass and thus reduce the exposure of the contents to light. It was developed to provide a highly protective laboratory glassware for handling materials sensitive to light in the 300- to 500-nm range (e.g., bilirubin, carotene, and vitamin A).

Flint glass is a soda-lime glass composed of a mixture of silicon, calcium, and sodium oxides. This type of glass is lowest in cost of all glasses and is readily fabricated in a wide variety of shapes. Such glass has poor resistance to high temperatures and sudden changes of temperature, and its resistance to chemical attack is only fair. Because this glass is relatively easy to melt and shape, it has been used for bottles and some disposable laboratory glassware. Certain manufacturers supply flint (soft) glass disposable pipettes to the

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

clinical laboratory. Users of such pipettes need to rinse the pipettes before use if they have not been water-rinsed by the manufacturer. Soda-lime pipettes may release alkali into the liquid inside the pipette and cause considerable errors in certain critical assay procedures (such as trace metal analyses). Organic contaminants found in soft glass and borosilicate glass disposable pipettes can also interfere with analytical procedures using UV-absorption or fluorescence techniques.

Colored and opal glasses, used in filters and light bulbs, are made by adding small amounts of metallic oxides to the glass.

Coated glass has a thin metallic oxide permanently fire-bonded to the surface of the glass. It can conduct electricity and has electronic applications as a heat shield to protect against infrared light and as an electrostatic shield to carry off charges.

Optical glass is made of soda-lime, lead, and borosilicate; because of its high optical purity, it is used in making prisms, lenses, and optical mirrors.

Glass-ceramics (Pyroceram) have high thermal resistance, chemical stability, and corrosion resistance, and they are useful for making hot plates, table tops, and heat exchangers.

Radiation-absorbing glass is made of soda-lime and lead, and is useful in preventing the transmission of high-energy radiation (e.g., γ-rays and x-rays).

Cleaning of Glassware

Laboratory glassware should be rinsed immediately after use and placed in a weak solution of a detergent until it is washed. Hazardous materials should be properly discarded, and their containers should be washed immediately rather than placed with the glassware that is handled by laboratory washing personnel. In many institutions, the glassware is then washed in an automatic washer, rinsed in a special rinse cycle, and then placed in an automatic dryer. The manufacturer of the equipment should be able to recommend a detergent that is compatible with the equipment and effective with the local water supply. Residual detergent may be detected by measuring the pH of water added to the glassware, or by using a dilute solution of an acid-base indicator that will indicate an alkaline residue.

For general washing without an automatic washer, most laboratories prefer *detergents* that are not highly alkaline, are nonionic, and are metal-free. These have largely replaced the harsh alkaline detergents formerly used that, although effective, etched glassware and were hard on the skin. Again, special care must be taken to ensure adequate rinsing. All clean laboratory ware should drain with a continuous thin film of water. Imperfect wetting or the presence of discrete droplets of water indicates that the vessel is not sufficiently clean.

Ultrasonic cleaners may also be used to supplement the action of detergent. In these baths, where very-high-frequency vibrations cause the residue to be broken free from the walls of the vessel, neutral detergents are usually preferred.

Air drying or oven drying at temperatures below 100 °C, with the laboratory ware bottom up, is the preferred drying method. Occasionally, it is desirable to rinse the glassware with a water-miscible organic solvent and then to expose it to a stream of air or nitrogen. To prevent contamination, the solvent must be of high quality, and the gas must be pure. Storage should be such that the laboratory ware is protected from dust.

Plastic Ware

Plastic beakers, bottles, flasks, graduated cylinders, funnels, centrifuge tubes, tubing, and pipettes are widely used in clinical laboratories and have unique qualities that make them ideal for use when high corrosion resistance and unusual impact and tensile strength are required. The physical and chemical properties of various resins that are used in the preparation of laboratory plastic ware are listed in Table A1-5. The resistances of plastic ware to various chemicals are listed in Table A1-6. However, this information is intended to be used as a general guide only. Because many factors can affect the chemical resistance of a given product, it is important to test the material under your own conditions. If any doubt exists about specific applications of plastic laboratory ware, the manufacturer should be contacted.

Types of Plastic ware

Polyethylene and *polypropylene* are types of plastic used primarily to fabricate bottles, beakers, jars, carboys, jugs, funnels, pipette jars, pipette baskets, tanks, buret covers, check valves, disconnect valves, twist lock connectors, needle valves, hollow stoppers, dropping pipettes, hydrometer jars, stirring rods, tubing, and reagent dispensers. Polyethylene is less expensive than polypropylene and is used in most disposable plastic ware. Polypropylene has a distinct advantage in that it withstands higher temperatures and can be sterilized; however, it absorbs pigments and tends to become discolored.

The *polyolefins* are a unique group of resins that are chemically relatively inert. Although concentrated sulfuric acid does slowly attack polyethylene at room temperature, the polyolefins as a group are unaffected by acids, alkalis, salt solutions, and most aqueous solutions. Aromatic, aliphatic, and chlorinated hydrocarbons cause moderate swelling of the plastic at room temperature; organic acids, essential oils, and halogens slowly penetrate these plastics. Strong oxidizing agents attack this group of resins only at elevated temperatures.

Polycarbonate is twice as strong as polypropylene and may be used at temperatures ranging from −100 °C to +160 °C; however, its chemical resistance is not as wide as that of the polyolefins. This resin is unsuitable for use with strong acids, bases, or oxidizing agents; it is dissolved by chlorinated aliphatic and aromatic hydrocarbons. Polycarbonate resin is insoluble in aliphatic hydrocarbons, some alcohols, and

*Except for oxidizing acids; for oxidizing acids, see "Oxidizing Agents, Strong."

dilute aqueous acids and salts. Because laboratory ware molded from this resin is clear glass and shatterproof, polycarbonate is used extensively in centrifuge tubes and graduated cylinders.

Fluorocarbon resins (Teflon) have unique qualities that make them almost chemically inert and therefore ideal when high corrosion resistance at extreme temperatures is essential. Because Teflon (fluorinated ethylene propylene [FEP]) resists extreme temperatures ranging from −270 °C to +255 °C, bottles and beakers made of this material are suitable for use in cryogenic experiments.

Laboratory ware made of fluorocarbon resins (e.g., Teflon) is pure, translucent, white, and inert to such corrosive reagents as boiling aqua regia, nitric and sulfuric acids, boiling hydrocarbons, ketones, esters, and alcohols. Because of its unique antiadhesive properties and its nonwettable

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

surface, Teflon is used for self-lubricating stopcocks, stirring bars, bottle cap liners, and tubing. It is also quite easy to clean and is fast drying, but it can easily be scratched and warped.

Use, Care, and Cleaning of Plastic Ware

Whenever possible, plastics should be used in place of glass, because plastic ware has the advantage of being unbreakable and does not release ions into a solution as does glass. Two disadvantages of plastic ware are a tendency to bind various solutes and to leach surface-bound constituents into subsequent solutions. Polyethylene is permeable to water vapor, and even in tightly stoppered bottles evaporation may occur, resulting in an increased concentration of the reagents and calibrators. As the volume of remaining liquid diminishes to a small fraction of the total capacity, the ratio of the surface area to volume increases; with the increased surface area of polyethylene available for diffusion, evaporation becomes a significant factor. Therefore small volumes of reagent should never be stored in oversized plastic bottles for long periods of time.

Polyethylene is not completely inert and may bind or adsorb proteins, dyes, stains, iodine, and picric acid. Colorless reagents may bind to plastic ware without being detected, only to manifest themselves in subsequent chemical analyses as a cause of erratic results. Slow reduction of ceric and cuprous ions has been observed in solutions stored in polyethylene bottles. Such solutions may also develop significant fluorescence after being stored in plastic containers for extended periods.

Linear polyethylene, polypropylene, Teflon, polymethylpentene, and polycarbonate plastics can be cleaned in ordinary glassware washing machines. Ultrasonic cleaners may also be used provided the plastic ware does not rest directly on the transducer diaphragm. The use of abrasive cleaners and strong oxidizing agents should be avoided.

Polypropylene, Teflon, and polymethylpentene may be repeatedly autoclaved under normal conditions. Polycarbonate shows some loss of mechanical strength when autoclaved; thus this procedure should be limited to 20 minutes at 121 °C. Plastic ware should be well cleaned and rinsed with deionized water before sterilizing because certain chemicals that have no appreciable effect on plastics at room temperature may cause deterioration at autoclaving temperatures. Polystyrene, polyvinyl chloride, styrene acrylonitrile, and conventional polyethylene are not autoclavable, but they may be gas sterilized with ethylene oxide or chemically sterilized by rinsing with benzalkonium chloride. With the exception of Teflon, none of the listed resins should be hot-air sterilized because of the potential for accelerated oxidative degradation.

Some of the transparent plastics (e.g., polycarbonate, polystyrene) may absorb minute quantities of water vapor and appear cloudy after autoclaving. This clouding effect is transient and disappears as the plastic dries. Clearing of the plastic may be accelerated by drying the plastic ware in an oven at 110 °C.

Synthetic and Rubber-Base Tubing

Tygon is a modified polyvinyl plastic substance that is clear and resistant to chemical attack and is used extensively for the manufacture of tubing. It is inert to most chemicals and has been used to transfer liquids, gases, and colloidal suspensions. It comes in a variety of sizes and is specified by inside diameter (i.d.), outside diameter (o.d.), and wall thickness. The tubing is rapidly and easily used and can be readily changed to meet specific needs. Because Tygon tubing is flexible, it can curve around corners and avoid obstructions. It occupies a minimum of space and can be used with a variety of positive-action (peristaltic) fluid pumping systems. Because it is available in continuous lengths, Tygon requires few joints or couplings. It is readily cut with a sharp blade and can be coupled to other, larger-bore Tygon tubing by using a small amount of solvent (cyclohexanone) to soften and bond the tubing ends. Careful heating of the tube ends with a hot metal probe can also assist in softening the plastic for coupling.

Tygon tubing is sometimes difficult to slip over metal or glass in making a connection. The use of a soapy solution or a synthetic wetting agent has the effect of lubricating the tubing, allowing it to slip on more easily. Various Y, H, and T fittings can also be used to join branch lines and make multiple connections with Tygon tubing. Simple collar clamps can serve to ensure a connection on glass or metal. Tygon is not compatible with polystyrene and acrylics and, when in contact at high temperatures with solutions containing zinc or copper, can become discolored.

Teflon tubing is also available and is chemically inert to synthetic substances, organic solvents, acids, and alkalis and can withstand continuous temperatures to 300 °C. It can be used in place of Tygon in circumstances requiring its special properties.

Amber *latex* rubber tubing is translucent and is recommended for all kinds of glass connections in which a highly elastic tubing with a long life is required.

Neoprene is a synthetic rubber that is soft and pliable and has a smooth finish. Neoprene is not affected by oil, alkalis, hot water, and many corrosive substances. It is not recommended for use with chlorinated or aromatic hydrocarbons.

Burets

A buret is a graduated tube with a small aperture and stopcock for delivering measured quantities of liquid or for measuring the liquid or gas received or discharged. Standard burets vary in size from 1 to 100 mL. A buret of 50-mL capacity is subdivided at 0.1-mL intervals. Burets having a capacity of 10 mL or less are classified as microburets.

The outflow of liquid from the buret is usually controlled by an all-glass or all-Teflon stopcock. The latter type does not require any lubricant and is especially useful when the titrant is an alkali. The all-glass stopcock should be lightly greased with petrolatum-like lubricants. Silicone-containing lubricants are not recommended, because they "creep" along

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

the length of the buret and subsequently contaminate its walls. Some burets are equipped with a reservoir and a two-way stopcock for self-filling.

A buret calibration is verified by first filling the buret to a point just above the zero line with CO_2-free deionized water and then by carefully adjusting the meniscus to the zero line. The drop of water adhering to the buret tip is removed by touching the tip to the inside of a glass vessel. A tared vessel is placed beneath the tip, and the buret is fully opened. Delivery should proceed freely with the buret tip not in contact with the vessel wall until the meniscus is about 1 cm above the graduation line of the desired volume. The buret tip should then be touched to the wall of the container and the content allowed to drain into the solution until the meniscus reaches the graduation mark. The tared vessel is then stoppered and reweighed, and the delivered volume corrected for temperature. As in the case with graduated pipettes, the accuracy of the overall calibration and mark-to-mark calibration decreases with a decrease in buret size.

Burets used in macroanalysis have major graduation marks completely around the long cylindrical tube and minor graduation marks at least halfway around. Errors of parallax in reading the meniscus are thus minimized at the major graduations but may still occur at the minor graduations.

Microburets

Microburets are used to deliver liquids in the microliter range. Some microburets are constructed like a syringe. The plunger of the syringe can be machined to an exact diameter. The displacement by the advancing plunger is indicated on a micrometer dial and is proportional to the volume delivered.

Various sizes are available that permit accurate delivery of as little as 0.01 μL per scale division. Several points should be noted:

1. The titrant must be prepared at a relatively high concentration to reduce the volume necessary for a titration and to provide sharp end points. For example, if an end point can be determined to ±1 scale division, the volume of titrant in an average titration should be equivalent to 100 scale divisions to provide a precision of ±1%. The concentration of titrant is a compromise between choosing a weaker concentration, which provides a larger volume and therefore a smaller reading error, and a stronger concentration, which minimizes end point error and avoids overdilution of the sample.
2. The tip of the buret must be placed beneath the surface of the solution to be titrated to permit even dispensing of reagent and to avoid discrete drop formation. The tip must be drawn to a fine point to prevent diffusion of liquid back into the buret.
3. Titrations must be performed with good lighting against a white background to permit easier detection of color changes, and the solution must be stirred as the titration proceeds. For titration in test tubes, the solution may be mixed with a fine stream of air or bubbles of an inert gas. Vibrators or small cups that are rotated electrically also ensure mixing during the titration. Magnetic stirrers with very small stirring bars (e.g., 1×5 mm) are available commercially.
4. Blanks and calibrators must be included routinely and titrated to the same end point as the unknown. Indicator error is more significant in microtitrations; it is therefore advisable to pipette a fixed volume of indicator rather than to add it by a dropper. Duplicate determinations are recommended.

CALIBRATION OF VOLUMETRIC PIPETTES

Accurate calibration or verification of calibration of pipettes, dispensers, and dilutors can be calibrated with gravimetric and spectrophotometric procedures.

Gravimetric Procedure

Gravimetric measurement of dispensed aliquots of water with density correction is a useful technique for verifying the calibration of volumetric devices.

1. Ensure that water, weighing vial, and pipette are at room temperature at the time of the procedure.
2. Determine and record the temperature (t) of a large volume of pure water to the nearest whole degree.
3. Weigh a clean, dry, empty, stoppered weighing vial. Handle the vial without touching it with bare fingers. Record weight to nearest 0.1 mg (W_v).
4. Transfer a sample of water to the weighed vial.
5. Restopper and reweigh the vial. Record weight to the nearest 0.1 mg (W_f).
6. Refer to the table entitled "True Capacity of Glass Vessels from the Weight of the Contained Water or Mercury When Weighed in Air" in *Handbook of Chemistry and Physics* to obtain the correction factor (F_t) for the water temperature.
7. Calculate the volume delivered (VD) using the following algorithm:

$$\mathrm{VD(mL)} = (W_f - W_v) \times F_t$$

Example for a 10-mL pipette
$W_f = 31.9961$ g
$W_v = 22.0391$ g
$t = 24$ °C
$F_t = 1.003771$
Therefore

$$\mathrm{VD} = (31.9961 - 22.0391 \times 1.003771) = 9.9945\,\mathrm{mL}$$

The deviation, or error, from stated capacity is

$$\frac{(10 - 9.9945)}{10} \times 100 = 0.055\%$$

In routine analysis, an error of 0.1% or less may be ignored when using a pipette. With an error in excess of 0.1%,

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

depending on the application, the stated capacity of a given pipette may require correction to the actual capacity found.

Spectrophotometric Procedure

As an alternative to gravimetric calibration, a convenient method is to use a compound that absorbs light to verify the calibration of volumetric devices. The following is an example of the use of *p*-nitrophenol in a spectrophotometric verification of the calibration of a 10-µL pipette.

1. All glassware used should meet Class A specifications.
2. Reagents required:
   (a) NaOH, 10 mmol/L
   (b) *p*-nitrophenol, 1.050 g/L
3. Preparation of reagent:
   Dissolve 105 mg of high-purity *p*-nitrophenol (NIST SRM 938) in deionized water in a 100-mL volumetric flask. Fill to the mark.
4. Preparation of dilutions:
   a. Reference dilutions: Fill three 250-mL volumetric flasks to the mark with 10 mmol/L NaOH. To each, add 1.0 mL of the *p*-nitrophenol solution, using a different volumetric pipette for each addition.
   b. Test dilutions: Add to each of five test tubes 2.5 mL NaOH, 10 mmol/L, using either a calibrated pipette or calibrated dispenser. To each tube, using the test micropipette in the correct delivery mode, add 10 µL of *p*-nitrophenol solution. (If the pipette is the "to-deliver" [TD] type, and is being rinsed in receiving solution, set aside a portion of *p*-nitrophenol for rinsing the pipette between each of the five additions.)
5. With a narrow bandpass spectrophotometer, read the absorbance of each of the reference and test dilutions at 401 nm in 10-mm cuvets. For NIST *p*-nitrophenol SRM with a "certified absorptivity" of 131.48 $L \cdot g^{-1} \cdot cm^{-1}$ in NaOH, 10 mmol/L, A_{401} should be 0.550 for an exactly prepared reference dilution. Average the readings of the three reference dilutions; the mean value (A_1) should be close to 0.550. Average the five test dilution readings for a mean value (A_2).
6. Calculation:

$$\text{Volume delivered (µL)} = \frac{A_2}{A_1} \times D \times V$$

where D is dilution of test solution (1/251 in this example), and V is final volume in microliters of the test dilution (2510 µL in this example).

For this example then, if A_1 is 0.550 and A_2 is 0.561, the volume dispensed was 10.20 µL ($0.561/0.550 \times 1/251 \times 2510$ µL). Because the nominal capacity of the volume dispensed by this pipette is 10 µL, a dispensed volume of 10.20 µL is a 2% error. The analyst must make a decision as to the acceptability of this error. As supplied by the manufacturer, micropipettes of this capacity are capable of delivering between 0.5% and 1% of nominal capacity, depending on the type of pipette.

CENTRIFUGATION

Components of a Centrifuge

All centrifuges contain a rotor or centrifuge head, a drive shaft, and a motor. The rotor is enclosed in a chamber that is provided with a cover and latch. Most centrifuges also include a power switch, timer, speed control, tachometer, and brake. Some include a protective shield to minimize aerosol production if a tube should break, or a refrigerator to reduce the temperature within the chamber. Most modern centrifuges contain a programmable microprocessor that can control the acceleration and deceleration of the rotor as well as the overall running time. For a particular type of specimen, the necessary program can be recalled from memory to ensure reproducible separations. Centrifuges may also include audible or visible alarms to indicate malfunctions, such as imbalance of the rotor.

The typical design of a horizontal-head rotor allows the use of four buckets, each able to swing freely between x-shaped metal limbs. The buckets are suspended from support pins placed into grooves in the limbs. The buckets can accept a variety of racks or adapters into which the tubes to be centrifuged are inserted. For any one model of centrifuge, the buckets serve as the tube holders and are interchangeable. Most tube holders contain cushioning pads to lessen the possibility of tube breakage during centrifugation. In some bench top centrifuges, as many as 60 tubes may be inserted into a single rack, allowing a theoretical capability of centrifuging 240 tubes at one time.

The drive-motor of a large centrifuge is usually a high-torque, heavy-duty DC electrical motor of up to 560J/s HP. AC motors are usually used with small centrifuges. Diodes and capacitors are used to rectify the alternating current. The rotor shaft usually is driven directly or through a gyro system, but occasionally a pulley system is used. In most centrifuges, sealed bearings are used to reduce the need for lubrication and to minimize vibration. The speed of the centrifuge rotor is governed by a potentiometer, which changes the voltage supplied to the motor. However, differences in the load to be spun cause the rotor to turn at different speeds although the potentiometer setting is the same. The tachometer indicates the speed of the rotor in revolutions per minute (rpm), not the gravitational force applied to the contents of the tubes in the rotor. The brake operates by reversing the polarity of the current to the motor, thus causing rapid deceleration.

The timer on a centrifuge allows a rotor to reach a preprogrammed speed under optimized conditions and then decelerate without braking after the set time. Most centrifuges can be operated independently of a timer.

Because centrifuges generate heat, the temperature in the chamber in many centrifuge models may increase by as

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

much as 5 °C after a single run. The change in temperature depends on the initial ambient temperature in the centrifuge chamber, rotor speed, duration of centrifugation, and rotor design. These factors affect the concentration of analytes in a specimen due to loss of water caused by evaporation. A large chamber around the rotor dissipates heat. When the material to be centrifuged is temperature-labile, a refrigerated centrifuge should be used. In the simplest form, a refrigerator unit is mounted beside the centrifuge, and cold air is blown into the rotor chamber. This approach is usually inadequate to stabilize the low temperature. In more sophisticated centrifuges, refrigeration coils around the chamber make it possible to maintain a preset temperature within ±1 °C.

Some models of centrifuges are available with a plastic cover over the rotor chamber or over each swinging bucket to reduce aerosol formation when a tube breaks during centrifugation.

PROCEDURES FOR CONCENTRATING SOLUTIONS

Evaporation is a technique most often used to concentrate solutes in a solution, particularly low-molecular-weight solutes. A technique frequently used for the evaporation of volatile solvents is to direct a stream of air through a fine nozzle onto the surface of liquid in a tube to flush out vapors in equilibrium with the solution. With a suitable manifold, this procedure can be applied to many tubes simultaneously, and the procedure can be speeded up by placing the tubes in a heated water bath. The procedure should be carried out in a fume hood to prevent a health hazard resulting from evaporating solvents. If compressed air is used, it should be passed through a filter and over a desiccating agent to prevent particulate matter and moisture from contaminating the solution.

Rapid removal of large volumes of solvent is best effected through a combination of reduced pressure and heat. The solution to be evaporated is placed in a round-bottom flask of a capacity no larger than 100 mL to avoid the danger of implosion. Vacuum is applied to the flask through a safety trap while the flask is swirled in a heated water bath. Swirling produces a large surface area, thus speeding evaporation and reducing bumping. Alternatively, a thick-walled Erlenmeyer flask may be used at ambient temperature. A water aspirator, an institution vacuum line, or a mechanical vacuum pump may be used to reduce the pressure. With any system, a suitable trap is essential to collect the vapors.

To concentrate a larger volume of solution, a rotary evaporator is used. To concentrate many specimens of small volume, vortex evaporators or multiple unit rotary evaporators are available.

Freeze-drying (lyophilization) has been extensively used in laboratory medicine for the preparation of calibrators, control materials, reagents, and to a lesser extent, individual specimens for analysis. More than 99% of the water in a substance to be freeze-dried may be removed in the typical freeze-drying process. The composition of the freeze-dried material is usually unchanged by freeze-drying except for the loss of water or some volatile organic matter. Freeze-drying first entails freezing a material at −40 °C or less and then subjecting it to a high vacuum. Very low temperatures cause the ice to sublime; solid nonsublimable material, initially locked in an ice matrix, remains behind in a dried state.

Commercial freeze-drying instruments allow many specimens to be dried at the same time by means of special manifolds. Such instruments usually combine a freezer unit with a lyophilizer. In the most sophisticated systems, the temperature and vacuum may be adjusted according to the material to be processed. Freeze-drying is most efficient (i.e., drying is most rapid and the material does not thaw) when the material to be dried is spread as a thin film over the inner surface of a flask or other container. This is best accomplished when the container is rotated during freezing. The volume of material to be lyophilized may vary from a few milliliters to several liters.

SEPARATORY FUNNELS AND EXTRACTION PROCEDURES

Separatory funnels are used in the clinical chemistry laboratory for simple extraction procedures. These involve bringing a given volume of solution into contact with a given volume of solvent (immiscible in the solution) and shaking until equilibrium has been attained; this is followed by separation of the liquid layers. Most separatory funnels taper off to a narrow bottom that contains a sealed stopcock. Thus it is relatively easy to separate two phases for further analysis. The capacity of the funnel should be such that the liquids occupy no more than approximately one half the volume of the funnel. If necessary, the extraction procedure may be repeated after the addition of fresh solvent. This type of extraction gives rapid, simple, and clean separations. When extracting from a liquid to a lighter solvent, as in diethyl ether extractions of aqueous solutions, it is necessary to remove the lower phase from the funnel after each extraction before removing the extraction solvent.

Extraction is the process used to separate compounds on the basis of their different solubilities in different solvents. The technique may be used either to purify or to concentrate a material.

The choice of solvent for extraction depends on the solute to be recovered. In general, it is desirable to use a solvent that does not form emulsions and is easily evaporated. Diethyl ether and ethyl acetate are commonly used, although both tend to absorb water. Diethyl ether, although having the advantage of being easily evaporated, is toxic and is capable of forming explosive peroxides; it is also a fire hazard. In some cases, an emulsion forms that consists of a colloidal suspension of the organic solvent in the aqueous solution, or vice versa. Emulsification occurs most often when the solute acts as a detergent or when viscous solutes are present.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

Emulsification is less likely to occur when the two solvents are swirled together rather than shaken vigorously. An emulsion may be broken by the addition of an inorganic salt soluble in water ("salting out"), which reduces the solubility of organic solvents in water. Among other techniques that may be effective are the addition of a silicone defoamer, a detergent, an acid, or several drops of ethanol or diethyl ether; the last of these is especially useful when the organic layer is chloroform. An emulsion may also be resolved by allowing it to stand or by centrifugation.

When water and an immiscible solvent have been shaken together, the two phases may be separated by *phase separation paper* (Whatman 1 PS Phase Separator). This paper has been impregnated with a special silicone to make it hydrophobic, so that the paper retains water. When the paper is folded in the conventional way in a conical filter funnel, solvents that are heavier than water flow through the apex. Solvents that are lighter than water pass through the wall of the folded cone.

LABORATORY MIXERS AND HOMOGENIZERS

Efficient mixing of solutions of very different densities is facilitated by mechanical agitation. Laboratory mixers differ mainly in the design of the motor and the stirrer. Depending on the application, a fixed- or variable-speed motor should be selected. For viscous solutions, high-torque, low-speed motors should be used. In the presence of explosive vapors, an air-driven motor should replace electrical motors. The speed of rotation of this motor and stirrer is changed by altering the air pressure.

Laboratory mixers are rated according to whether they are for continuous (8 hours uninterrupted) or intermittent duty. The design of the rotating device is dictated by its intended application, such as shearing, mixing, or homogenizing. Most stirrers are made of glass, stainless steel, or Teflon. Although most mixers are intended for bench top use, certain models are driven by 12-V DC motors and may be held by hand above the vessel in which solutions are to be mixed. Solutions in a flask may also be mixed by placing a Teflon-coated stirring bar in the flask and placing it above the stirring module that contains a rotating magnet.

Measurements on cell contents require initial preparation of the tissue. Preparation may involve grinding of the tissue in a ground-glass tissue blender using manual force or a rotor driven by a simple electrical motor. For large quantities of material, a tissue blender similar to the typical kitchen blender is used to emulsify and pulverize the tissue. Several different designs of blades are available and may easily be exchanged if a different application is required. The speed at which the blades rotate is usually more than 15,000 rpm.

FILTRATION

Two types of filtration are used to separate particles from liquids: *surface* filtration and *depth* filtration. *Surface filtration* (screen filtration) is performed with filter papers, membranes, or sieves. The process is one of exclusion of the particles having a larger diameter than the pores of the separation medium. Surface filtration retains the solid material on the filter medium, and the filtrate passes through the filter to be collected or discarded as required. The number and size of pores can be accurately controlled in the manufacture of the separation medium so that it is possible to determine the appropriate filter for a given task.

With *depth filtration,* the thick separation medium allows particles to be retained in the body of the filter as well as on the surface. Depth filters are usually made of cotton, fiberglass, asbestos, or other materials such as diatomaceous earth. In depth filters, the matrix of fibers is usually arranged in a random manner to eliminate channels through the filters but to still allow passage of fluid. Combining depth and surface filters into a single filter is useful for purifying solutions. The depth filter is used as a prefilter to trap large particles, thus lengthening the life of the secondary surface filter. Fiberglass or sintered glass is often used as a refilter for coarse materials.

Filtration may be conducted under gravity or pressure, or in a vacuum. The last may be used to accelerate the filtration rate by combining the influence of gravity, suction, and capillary attraction. The factors affecting gravity filtration include the nature of the filter medium, its surface area, and its pore size. The number and size of particles in solution and the solution's pH may also affect the filtration rate.

Many filtrations in the clinical laboratory are carried out with *filter paper.* Different types of filter paper include low-ash or ashless paper as well as various grades related to thickness. Regular filter paper leaves some ash on ignition and thus cannot be used in gravimetric analysis. Ashless paper can be used in gravimetric analysis because it leaves such a low residue on ignition that its mass can be ignored. Vacuum filtration requires paper known as *hardened-grade paper,* with high, wet tensile strength. Fiberglass papers have the greatest strength and combine the advantages of retention of fine particles with fast filtration. Table A1-7 describes the grade, flow rate, and retention characteristics of commonly used filter papers. *Retention* refers to the particle size of precipitate the grade will retain; *speed* refers to relative mean flow rates.

Filtration can also be carried out with *membranes* of controlled pore size. These filters are made from homogeneous polymeric materials, such as polyvinylidene fluoride, cellulose esters, cellulose acetate, polytetrafluoroethylene, and polyvinyl chloride, depending on the intended application of the filter. The most widely used filter is composed of cellulose acetate and cellulose nitrate. The filters contain no loose fibers or particulate matter and are manufactured in a variety of sizes up to almost 30 cm in diameter and with pore sizes that vary from 10 to 0.025 μm, the latter being capable of sterilizing the filtrate by retaining microorganisms. Eighty percent of the surface area of a typical membrane filter is

†Time taken for 100 mL of clean water to pass through 15-cm quadrant-folded circle, according to a modified ASTM method D981-56.

occupied by pores, so that high flow rates occur through a filter even with pores of the smallest diameter. The basic structure of membrane filters is hydrophobic, although the surface of the membrane can be modified chemically to make it hydrophilic.

Membrane filters may be used under vacuum, with positive pressure, or with gravity. Some filter holders have been designed for use with syringes through which pressure is applied to filter a solution. Filters have been incorporated into certain disposable tips for use with semiautomatic pipettes. These filters minimize the exchange of aerosol droplets between the tips and the pipette. This is of particular importance for DNA amplification and microbiological procedures. Other membrane filters are designed for ultrafiltration and are available with a variety of pore sizes for selective filtration. *Ultrafiltration* is a technique for removing dissolved particles using an extremely fine filter. It is used to concentrate macromolecules, such as proteins, because smaller dissolved molecules pass through the filter.

Many small specimens of biological fluids may be concentrated at the same time using porous *cellulose acetate filter* cones and a centrifuge. The filter cones fit inside centrifuge tubes, and centrifugal force is used to drive water and molecules with a molecular weight of less than 50,000 Da through the anisotropic membrane filter. This approach is widely used to concentrate proteins in urine or cerebrospinal fluid in preparation for electrophoretic analysis.

Fine hollow-fiber filters with walls of well-defined porosity are now also used to produce ultrafiltrates or to concentrate proteins. The large filter surface allows rapid concentration.

APPENDIX 14

Selection and Analytical Evaluation of Methods—With Statistical Techniques

Kristian Linnet, M.D., and James C. Boyd, M.D.

STANDARD ERRORS OF PERCENTILES

For specified, theoretical distributions, a general, approximate expression for the standard error (SE) of a nonparametrically estimated percentile corresponding to the percentage p can be given as

$$SE_{npar} = \left[(p/100)(1-(p/100))/(d^2N)\right]^{0.5}$$

where d is the density of the distribution at the percentile and N is the sample size.[45*] For Gaussian distributions, we have for the 5 and 95 percentile

$$SE_{npar} = \left[0.95(1-0.95)/((0.10311^2/\sigma^2)N)\right]^{0.5} = 2.114\sigma/N^{0.5}$$

and for the 2.5 and 97.5 percentile

$$SE_{npar} = \left[0.975(1-0.975)/((0.05844^2/\sigma^2)N)\right]^{0.5} = 2.672\sigma/N^{0.5}$$

For real data sets, estimation of the densities in the tails of a distribution is not practical. Instead, confidence limits for nonparametrically estimated percentiles can be derived from the ranked observations.[33] For example, given 120 observations, the 90%-confidence interval for the 2.5 percentile extends from the value of observation 1 to 7. For the 97.5 percentile, the 90% confidence interval is, from observation, 114 to 120. For smaller sample sizes, SEs of percentiles can conveniently be estimated by the bootstrap procedure, and confidence intervals are then derived[70] (see below).

The standard error of a parametrically estimated percentile given a Gaussian distribution is

$$SE_{par} = \sigma\left[1/N + z^2/(2N)\right]^{0.5}$$

where z is the standard Gaussian deviate for the given percentile.[61] For the 5 and 95 percentiles, the relation is

$$SE_{par} = \sigma\left[1/N + 1.645^2/(2N)\right]^{0.5} = 1.534\sigma/N^{0.5}$$

and for the 2.5 and 97.5 percentiles

$$SE_{par} = \sigma\left[1/N + 1.96^2/(2N)\right]^{0.5} = 1.709\sigma/N^{0.5}$$

The asymptotic efficiency of the nonparametric percentile estimation procedure is

$$(1.534/2.114)^2 = 0.527$$

for the 5 and 95 percentile and 0.409 for the 2.5 and 97.5 percentile. Thus, if a parametrically estimated 95 percentile is based on 100 observations, 190 observations are required by the nonparametric procedure to provide the same precision of the estimate.

*References are found in Ch. 14 of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnosis,* edition 4.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

ESTIMATION OF POOLED STANDARD DEVIATION

When SD is estimated from repeated measurements of several (K) samples, a pooled estimate is formed from the weighted average of the variances (squared SDs) as

$$SD^2 = \left(n_1SD_1^2 + n_2SD_2^2 + n_3SD_3^2 + \ldots + n_kSD_k^2\right)\Big/ (n_1 + n_2 + n_3 + \ldots + n_k)$$

where n_k ($n_k = N_k - 1$) refers to the degrees of freedom for the sample with number k (i.e., the k^{th} sample is assayed N_k times).

COEFFICIENT OF SKEWNESS

This coefficient, γ_1, measures the symmetry of a distribution. We have

$$m_2 = \sum (x_i - x_m)^2 \Big/ N$$
$$m_3 = \sum (x_i - x_m)^3 \Big/ N$$
$$\gamma_1 = m_3 \Big/ m_2^{3/2}$$

The value is zero for a Gaussian distribution, positive for a distribution with a tail to the right, and negative for a distribution skewed to the left side.[61]

COEFFICIENT OF KURTOSIS

This coefficient, γ_2, measures the "flatness" of a distribution. We have

$$m_2 = \sum (x_i - x_m)^2 \Big/ N$$
$$m_4 = \sum (x_i - x_m)^4 \Big/ N$$
$$\gamma_2 = \left(m_4 \Big/ m_2^2\right) - 3$$

The value is zero for a Gaussian distribution, positive for a "peaked" distribution, and negative for a "flat" distribution relative to the Gaussian shape.[61]

OUTLIERS

For a Gaussian distribution, the probability (P) of observing an observation a given (z) number of SDs from the mean can be read from a table of Gaussian probabilities. Notice, however, that the most deviating observation out of N observations is selected, i.e., for small P the probability that a given observation belongs to the distribution is NP.

Example: Gaussian distribution, limit = 4 SD.

$P = 0.00006334$	
$N = 50$	$NP = 0.003167$
$N = 100$	$NP = 0.006334$
$N = 200$	$NP = 0.012668$
$N = 500$	$NP = 0.03167$

Thus the default limit of 4 SD may be reasonable for Gaussian distributions with N up to about sample sizes of 200, where the probability is about or less than 0.01. Concerning nonnormal distributions, the probability may be higher, especially for skewed distributions.

Another principle is to look at the distance from a suspected outlier to the next largest observation.[19,97] From the ordered values, Dixon's range statistic DR is calculated:

$$DR = (x_N - x_{N-1})/(x_N - x_1)$$

The maximum sample value is deleted if the critical value is exceeded. In the field of clinical chemistry, a critical value of 0.33 is often used, but this is the 0.01 significance level for 30 observations from a normal distribution.[19] For normal distributions with $N = 100$, 200, or 500, the corresponding critical ratios are 0.26, 0.22, and 0.19 ($P = 0.01$), respectively. For a log-normal distribution with coefficient of skewness of 1.5 and the mentioned sample sizes, the critical values are 0.53, 0.48, and 0.44.[61]

JACKKNIFE PROCEDURE

The so-called jackknife method belongs to a class of nonparametric statistical procedures based on *resampling*, taking advantage of the capacity of modern computers. In principle, sampling variability is mimicked by repetitively resampling the original data set. Using the jackknife principle, one may calculate SDs and SEs on a nonparametric basis. One observation is left out at a time, and the parameter in question is estimated on the basis of the rest of the observations. Having successively eliminated each observation, a set of parameter estimates is obtained reflecting the variability of the data set. Using estimation of the regression slope as an example, the computations are as follows[107]

b^i = the slope based on the subset $\{(x_j; y_j)\}$, which does not contain $(x_i; y_i)$

$b_i = Nb - (N - 1)b^i$

$\left(\text{the } i^{th} \text{ pseudovariate, } i = 1, \ldots, N\right)$

where b is the slope estimated from the complete data set.

$$b_J = \sum b_i \Big/ N \quad \text{(the jackknifed estimator)}$$
$$V_j(b) = \sum (b_i - b_J)^2 \Big/ (N - 1)$$
$$SE(b) = \left[\sum (V_j(b)) \Big/ N\right]^{0.5}$$

BOOTSTRAP

The bootstrap procedure is a nonparametric, computer-based resampling principle for estimation of SEs.[22,107] The procedure consists of repeated random sampling with replacement from the original data set. For each so-called pseudosample, the statistic in question is computed (e.g., a percentile). By repetition a suitable number of times (e.g. 100 times) a set of values of the statistic is obtained that

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

reflect the sampling variation. The SE is then obtained as the SD of the 100 percentile pseudoestimates. On the basis of the SE, confidence intervals can be estimated. With regard to extreme percentiles, the sample size should not be too small (e.g., not less than 40 for the 2.5 and 97.5 percentiles).[70] In particular, the bootstrap procedure is suitable to assess variability of complicated expressions that cannot be handled by traditional mathematical closed formulas.

TABLE A14-8 (Supplement to Table 14-8) Data [N = 65 (x1, x2) Values] Used in the Comparison of Drug Assays Example

APPENDIX 21

Enzymes

Mauro Panteghini, M.D., Renze Bais, Ph.D., and Wouter W. van Solinge, Ph.D.

METHODS INCLUDED:

Method 21-1. Preparation of Hemolysate
Method 21-2. Determination of Glucose-6-Phosphate Dehydrogenase
Method 21-3. Screening Erythrocytes for Glucose-6-Phosphate Dehydrogenase Deficiency
Method 21-4. Determination of Pyruvate Kinase Activity
Method 21-5. Determination of Glucose Phosphate Isomerase Activity
Method 21-6. Determination of Erythrocyte Glutathione Concentration
Method 21-7. Screening for Deficiency of Pyrimidine-5′-Nucleotidase Activity
Method 21-8. Determination of 2,3-Diphosphoglycerate in Erythrocytes

METHODS WITH METHODOLOGICAL DETAILS

METHOD 21-1. PREPARATION OF HEMOLYSATE

Principle

This method describes the steps required to produce a hemolysate that can be used for quantitative determinations of G6PD, PK, and GPI activity. It is based on the hemolysis of a whole blood sample using a hemolyzing solution of Triton-X 100.

Reagents and Supplies

1. Sodium chloride (NaCl) 0.156 mol/L (isotonic saline); use and store at 0 °C to 4 °C.
2. Cellulose slurry. Place 5 g α-cellulose (Sigma Chemical Co., St. Louis) and 5 g microcrystalline cellulose, Sigmacell type 50 (Sigma Chemical Co.) in a 250-mL Erlenmeyer flask. Add cold (0 °C to 4 °C) isotonic saline to the 125-mL mark and stir gently for 2 minutes using a magnetic stirrer. (The slurry is stable at 0 °C to –4 °C for 3 working days.) Mix the slurry before each use but do not mix longer than necessary to obtain homogeneity (excessive mixing results in breakup of cellulose particles).
3. Hemolyzing solution (Triton-X 100). Place 25 mL Triton-X 100 (Sigma Chemical Co.) in a 600-mL beaker. Add 200 mL of distilled water. Place the beaker in lukewarm

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

water and allow the mixture to warm. Stir until completely dissolved, then add 5.0 mL EDTA, 0.27 mol/L, pH 7.0; 270 mL distilled water; and 0.25 mL β-mercaptoethanol. Mix thoroughly. The solution remains stable for 1 month at 0 °C to 4 °C.

Procedure

1. Removal of white blood cells and platelets.
   a. Place the syringes with their plungers removed in a vertical position in a rack, one syringe for each sample. Place beakers or paper towels beneath the syringes to collect or absorb saline.
   b. Place a 1-cm square of four-ply gauze in the bottom of each syringe barrel and tamp it down securely. Wet the gauze with a few drops of saline. Then pipette approximately 4 mL of cellulose slurry into each syringe with a transfer pipette, being careful that the gauze is not displaced. (The syringe should be filled to between the 2- and 3-mL marks after the saline has drained off.)
   c. Wash the cellulose bed with about 3 mL of isotonic saline and allow to drain thoroughly. Gently add 1 mL of well mixed whole blood to the cellulose bed. Allow the blood to flow into the cellulose material.
   d. Place a 15-mL centrifuge tube under each syringe. Gently add cold saline to fill the syringe and allow it to flow through. Repeat this step once more to wash all RBCs through the syringe. Bring the RBC eluate to a 15-mL volume with cold saline and mix; then centrifuge at 0 °C to 4 °C and 1500 × *g* for 5 minutes.
   e. Remove only the supernatant saline. Do not disturb the cells.
   f. Repeat the saline wash once. Again remove saline, this time leaving a volume of supernatant saline equal to that of the packed RBCs.
2. Preparation of hemolysate using Triton-X 100. Place 1.8 mL of hemolyzing solution in a 13 × 100-mm tube. Add 0.2 mL of well mixed RBC suspension prepared in step 1 earlier and mix well. The hemolysate may be kept at 0 °C to 4 °C up to 1 hour. Note: Prepare the hemolysate just before assay. Keep it at 0 °C to 4 °C, but not longer than 1 hour.

Method 21-2. Determination of Glucose-6-Phosphate Dehydrogenase

Principle

Glucose-6-phosphate dehydrogenase (G6PD) catalyzes the oxidation of glucose-6-phosphate to 6-phosphogluconate with a concurrent conversion of $NADP^+$ to NADPH. The activity of G6PD is determined by measurement of the rate in increase in NADPH concentration. Whereas $NADP^+$ is transparent to ultraviolet (UV) light, NADPH strongly absorbs UV light. Therefore the rate of increase in absorbance at 340 nm is the measure of enzyme activity.

Reagents

1. EDTA, 10.27 mol/L, pH 7.0. To 100.5 g sodium-EDTA · $2H_2O$ (MW 372.24), add approximately 900 mL distilled water and adjust to pH 7.0 with 0.1 M sodium hydroxide (NaOH). Add water and dilute to 1000 mL final volume. This reagent is stable up to 1 year at 4 °C.
2. Stabilizing solution. To 0.25 mL β-mercaptoethanol, add 5.0 mL EDTA, 0.27 mol/L. Adjust pH to 7.0 and dilute to 500.0 mL with distilled water. This solution is stable for 1 month at 4 °C.
3. Tris (hydroxymethyl) aminomethane (TRIS)-hydrochloric acid (HCl) buffer, 1 M TRIS/EDTA, 5 mmol/L, pH 8.0. To 60.6 g TRIS (MW 121.14), add 0.93 g disodium-EDTA · $2H_2O$ (MW 372.24) and 400 mL distilled water. Adjust to pH 8.0 with 0.1 mol/L HCl. Dilute. Then add water to 500.0 mL final volume. This solution remains stable up to 1 year at 4 °C.
4. Magnesium chloride ($MgCl_2$), 0.1 mol/L. To 10.2 g $MgCl_2$ · $6H_2O$ (MW 203.31), add distilled water to 500 mL. This solution remains stable up to 1 year at 4 °C.
5. NADP (Sigma Chemical Co., or other supplier), 2 mol/L. To β-NADP, sodium salt, 10.0 mg/vial, add 6.2 mL distilled water and mix to dissolve. This solution remains stable for 1 working day at 4 °C.
6. Reaction mixture. Combine and mix thoroughly TRIS-HCl, 6.0 mL; $MgCl_2$, 0.1 mol/L, 6.0 mL; NADP, 2 mmol/L, 6.0 mL; distilled water, 34.8 mL. Multiples of these volumes may be used to prepare a larger batch. Prepare 6.0-mL aliquots and freeze at <0 °C. Stability is for at least 1 month.
7. G6P (Sigma Chemical Co., or other supplier), mmol/L. d-G6P, monosodium salt, 500 mg/vial. Dilute to 6 mM/L with TRIS-HCl solution. Divide into 0.8-mL aliquots and freeze at –22 °C.
8. Drabkin's reagent (Sigma Chemical Co., or other supplier); contains 100 parts sodium bicarbonate, 20 parts potassium ferricyanide, and 5 parts potassium cyanide when reconstituted. Reconstitute with 1000 mL distilled water. This solution is stable for 6 months at room temperature in an amber bottle.

Equipment

1. 37 °C heating block
2. UV spectrophotometer
3. Refrigerated centrifuge
4. Visible-range spectrophotometer
5. Magnetic stirrer
6. Rack for suspension of syringes
7. Plastic syringes, 6 mL
8. Gauze sponges, 3 × 3, four ply
9. Acrylic cuvets

Procedure

1. Prepare cuvets as follows:

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

	Blank (μL)	Test (μL)
TRIS-HCl, buffer	100	100
$MgCl_2$, 0.1 mol/L	100	100
NADP, 2 mmol/L	100	100
Distilled water	580	580
Hemolysate	—	20
Stabilizing solution	20	—
or		
Reaction mixture, thawed and mixed	880	880
Hemolysate	—	20
Stabilizing solution	20	—

2. Mix and incubate at 37 °C for 10 minutes.
3. Add 100 μL G6P, 6 mmol/L, to each cuvet. Mix.
4. Measure and record the increase in absorbance at 340 nm at 37 °C for at least 10 minutes.

Determine Hemoglobin Concentration of Hemolysate

1. Pipette 3.0 mL of Drabkin's reagent into a disposable cuvet.
2. Add 200.0 μL (0.2 mL) of Triton hemolysate. Mix.
3. Allow to stand for 10 minutes at room temperature.
4. Read absorbance at 540 nm against a blank of Drabkin's solution.
5. Calculate hemolysate hemoglobin concentration from the cyanmethemoglobin calibration curve.

Calculation of Glucose-6-Phosphate Dehydrogenase Activity

Although nearly 2 mol of NADP are reduced for each mole of G6PD oxidized, calculation of this assay is based on the assumption that only 1 mol of NADP is reduced.

$$\text{G6PD} = \frac{804 \times \Delta A_{340}/\text{min}}{\text{Hb}}$$

where

ΔA340/min = change in absorbance per minute corrected for blank
804 = factor used to calculate units of enzyme activity per 100 mL of hemolysate
Hb = hemolysate hemoglobin concentration in g/100 mL
G6PD = activity of erythrocyte G6PD in U/g Hb

Reference Intervals

The reference interval (mean ± 2 SD) for G6PD in erythrocytes is 12.1 ± 2.09 U/g Hb (0.78 ± 0.03 MU/mol Hb). Values greater than 18 U/g Hb are often encountered in any condition associated with younger than normal RBCs (as in hemolytic anemias not due to G6PD deficiency), but are of no clinical significance.

Comments and Precautions

This G6PD assay reflects NADPH generated in both the G6PD- and the 6-phosphogluconate dehydrogenase (6-PGD)-catalyzed reactions. Correction for the 6-PGD generation of NADPH may be made by use of two additional cuvets: 6-phosphogluconate is added to one cuvet; to the other, both 6-phosphogluconate and G6P are added. This "Glock and McLean assay" then provides both the true G6PD activity and an assay for 6-PGD. However, for practical purposes, it does not seem warranted to incorporate these additional measurements and calculations. Deficiency of RBC 6-PGD has not yet been reported as a cause of hemolytic disease. Nor does normal 6-PGD activity obscure G6PD deficiency. Thus the simpler procedure is adequate for diagnostic purposes.

Performance of this assay at 37 °C departs from the World Health Organization (WHO) recommendation that the assay be done at 25 °C. Because the reaction rate is quite temperature sensitive, thermal control is essential, and it cannot be assumed that ambient temperature in all laboratories is 25 °C. Thus there is no inherent advantage in performing the assay at 25 °C. However, to avoid ambiguity, the assay values calculated may be expressed in International Units (U) (WHO; 37 °C).

It is convenient to express activity in units per gram of hemoglobin. However, it is somewhat more logical to express activity in terms of the number of RBCs represented in the hemolysate. To do this requires an independent RBC count of a suspension of the washed packed RBCs. From a practical standpoint, either expression is satisfactory. Units per gram of hemoglobin may be converted to U/1010 RBCs by the relationship

$$\text{U per } 10^{10} \text{ RBC} = 0.29 \times \text{U per g Hb}$$

Method 21-3. Screening Erythrocytes for Glucose-6-Phosphate Dehydrogenase Deficiency

Principle

In this screening test, $NADP^+$ is reduced to NADPH in both the G6PD and the 6-PGD reactions of the hexose monophosphate pathway. If G6PD activity is low, only a small quantity of NADPH is formed. This is reoxidized to $NADP^+$ by glutathione reductase present in RBCs, and no fluorescence is observed. In the presence of adequate

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

amounts of G6PD, the rate of reduction of $NADP^+$ substantially exceeds the rate of oxidation of NADPH by glutathione reductase, and enough NADPH accumulates in RBCs to be demonstrable by its fluorescence.

Specimen Collection

A blood specimen is collected with an anticoagulant such as EDTA, ACD, or citrate-phosphate-dextrose. The sample is stable for 1 week when stored at 4 °C. Minimum volume required is 0.2 mL, and the test can be performed on freshly drawn heparinized blood from sticking a finger or heel contained in a capillary tube.

Stock Reagent Mixture

1. To a 20-mL flask or plastic bottle, add 1 mL G6P, 0.1 mol/L; 1 mL $NADP^+$, 7.5 mmol/L; 2 mL saponin, 1 g/L; 3 mL TRIS-HCl buffer, 0.7 mol/L, pH 7.8 (add 0.75 mol [90.85 g/L] of TRIS and adjust to pH 7.8); 1 mL oxidized GSH, 8 mmol/L; and 2 mL water.
2. Mix. This reagent is stable for several months when frozen at −20 °C.

Procedure

1. Allow 5 to 10 minutes for the reagent solution to thaw. Label three glass tubes (12 × 75 mm) and pencil a tic-tac-toe grid on a piece of filter paper (Whatman No. 1) for patient, normal, and abnormal control.
2. Pipette 100 µL of reagent solution into each tube and pipette 10 µL of specimen and controls into the respective tubes containing the reaction mixture. Mix.
3. Immediately transfer a drop from each tube to filter paper and start a timer.
4. At 5 minutes and 10 minutes, repeat step 3.
5. Allow spots to dry completely and examine spots with a long-wave UV light.

Interpretation

Normal specimens show no fluorescence of the initial spot on the filter paper but a progressive increase in fluorescence at 5 and 10 minutes. Abnormal specimens show no fluorescence at times 0, 5, and 10 minutes.

Comments and Precautions

This screening test is simple and inexpensive; it can be performed in field surveys or in laboratories that lack UV spectrophotometers. In experienced hands, this semiquantitative procedure can give satisfactory results equivalent to those obtained with costly instruments. However, this screening test has some disadvantages. It should be used only when testing male subjects for G6PD deficiency. Female heterozygotes are often not detected with this method. Male blacks who are G6PD deficient and who have had recent hemolysis commonly have normal results. Although for the sake of simplicity this procedure was originally devised for use with whole blood rather than washed RBCs, occasionally leukocytosis (e.g., white blood cell count of 12×10^9 cells/L) causes spuriously normal results because leukocytes have relatively much greater G6PD activity than do RBCs. For this reason, it is advantageous to use saline-washed RBCs suspended in an equal volume of isotonic saline.

Reference

Beutler E. Red cell metabolism: A manual of biochemical methods, 3rd ed. Orlando: Grune & Stratton, 1984.

Method 21-4. Determination of Pyruvate Kinase Activity

Principle

In this assay, the PK reaction is linked with the lactate dehydrogenase (LD) reaction in which NADH is oxidized to NAD^+.

$$\text{Phosphoenopyruvate} + \text{ADP} \xrightarrow{\text{PK}} \text{Pyruvate} + \text{ATP}$$

$$\text{Pyruvate} + \text{NADH} \xrightarrow{\text{LD}} \text{Lactate} + \text{NAD}^+ + \text{H}^+$$

Because LD is present in excess, the rate of NADH oxidation is limited by the activity of PK. The reaction rate is measured by the rate of decrease in absorbance at 340 nm. Assays are performed at low substrate concentration with and without addition of fructose-1,6-diphosphate, because some PK variants associated with hemolysis have atypical reaction kinetics (and thus may exhibit "normal" activity at high substrate concentrations but lower than normal activity at lower substrate concentrations) or may show absence of enhancement by fructose-1,6-diphosphate, the allosteric activator of PK.

Reagents

1. NaCl, 0.156 mol/L. Use and store at 0 °C to 4 °C. It remains stable indefinitely.
2. EDTA, 10.27 mol/L, pH 7.0. To 100.5 g sodium-EDTA · $2H_2O$ (MW 372.24), add approximately 900 mL distilled water and adjust to pH 7.0 with 0.1 mol/L NaOH. Add water; dilute to 1000 mL final volume. This solution is stable up to 1 year at 0 °C to 4 °C.
3. Stabilizing solution. To 0.25 mL β-mercaptoethanol, add 5.0 mL EDTA, 0.27 mol/L, pH 7.0, and dilute to 500 mL with distilled water. This solution remains stable for 1 month at 0 °C to 4 °C.
4. TRIS-HCl buffer, 1 mol/L TRIS/EDTA, 5 mmol/L, pH 8.0. To 60.6 g TRIS (MW 121.14), add 0.93 g disodium-EDTA · $2H_2O$ (MW 372.24) and 400 mL distilled water. Adjust to pH 8.0 with 0.1 mol/L HCl. Dilute. To this add water to 500 mL final volume. This solution remains stable up to 1 year at 0 °C to 4 °C.
5. $MgCl_2$, 0.1 mol/L. To 10.2 g $MgCl_2 \cdot 6H_2O$ (MW 203.31), add distilled water to 500 mL. This solution remains stable up to 1 year at 0 °C to 4 °C.
6. Potassium chloride (KCl), 1 mol/L. To 18.6 g KCl (MW 74.55), add distilled water to 250 mL. This solution is stable indefinitely at 0 °C to 4 °C.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

7. NADH, 2 mmol/L (β-NADH, disodium salt; Sigma Chemical Co., or other supplier). Add distilled water to dilute to 2 mmol/L. Stability is for one working day at 0 °C to 4 °C, or freeze in reaction mixture.
8. LD, 60.0 U/mL (L-lactic dehydrogenase, type XVIII, from porcine heart; Sigma Chemical Co., or other supplier). Dilute to 60.0 U/mL with stabilizing solution. Stability is for 1 working day, or freeze in reaction mixture.
9. Reaction mixture. Combine and mix thoroughly.

TRIS-HCl buffer	3.0 mL
KCl, 1.0 mol/L	3.0 mL
$MgCl_2$, 0.1 mol/L	3.0 mL
NADH, 2 mmol/L	3.0 mL
LD, 60.0 U/mL	3.0 mL
Water, distilled	6.9 mL

Multiples of these volumes may be used to prepare a larger batch. Prepare 5.0-mL aliquots and freeze at −20 °C. Stability is for 3 months.

10. Phosphoenolpyruvate (PEP, trisodium salt; Sigma Chemical Co., or other source; 25 mmol/L). Dilute to 25 mmol/L with TRIS-HCl buffer. Divide into aliquots and freeze at −20 °C. It is stable for several months.
11. ADP, 30 mmol/L, sodium salt, 500 mg/vial. Dilute to 30 mmol/L with distilled water, considering percent purity, sodium content, and hydration; aliquot 400 µL and freeze at less than 0 °C. It is stable up to 3 months when frozen.
12. Drabkin's reagent (Sigma Chemical Co., or other source; contains 100 parts sodium bicarbonate, 20 parts potassium ferricyanide, and 5 parts potassium cyanide when reconstituted). Reconstitute with 1000 mL distilled water. This solution is stable for 6 months at room temperature in an amber bottle.

Equipment

1. 37 °C heating block
2. UV spectrophotometer
3. Refrigerated centrifuge
4. Visible-range spectrophotometer
5. Magnetic stirrer
6. Rack for suspension of syringes
7. Plastic syringes, 6 mL
8. Gauze sponges, 3 × 3, four ply
9. Acrylic cuvets

Procedure

Note: The assay is performed using hemolysate prepared as described earlier.

1. Prepare cuvets as follows:

	Blank (µL)	High Test (µL)	Low Test (µL)
TRIS-HCl buffer	100	100	100
KCl, 0.1 mol/L	100	100	100
$MgCl_2$, 0.1 mol/L	100	100	100
ADP, 30 mmol/L	50	50	20
NADH, 2 mmol/L	100	100	100
Distilled water	230	230	445
LD, 60 U/mL	100	100	100
Hemolysate	—	20	20
Stabilizing solution	20	—	—

or alternatively, use previously prepared reaction mixture thawed and mixed:

	Blank (µL)	High Test (µL)	Low Test (µL)
Reaction mixture	730	730	730
ADP, 4 mmol/L	50	50	20
Distilled water	—	—	215
Hemolysate	—	20	20
Stabilizing solution	20	—	—

2. Mix. Incubate for 10 minutes at 37 °C.
3. Add 200 µL of PEP solution (25 mmol/L) to the blank and high-test cuvets and 15 µL of the PEP solution to the low-test cuvet.
4. Mix.
5. Measure the decrease in absorbance at 340 nm and 37 °C for 12 minutes.

Determine Hemoglobin Concentration of Hemolysate

1. Pipette 3.0 mL of Drabkin's reagent into a disposable cuvet.
2. Add 200.0 µL (0.2 mL) of 1 : 20 hemolysate. Mix.
3. Place in the dark and allow to incubate for 10 minutes at room temperature.
4. Read absorbance at 540 nm against a blank of Drabkin's solution.
5. Determine the hemolysate hemoglobin concentration from a calibration curve.

Calculation of Pyruvate Kinase Activity

$$PK = \frac{804 \times \Delta A_{340}/\text{min}}{Hb}$$

where

PK = units of enzyme activity per gram of hemoglobin

804 = factor used to calculate units of enzyme activity per 100.0 mL of hemolysate

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

ΔA_{340}/min = change in absorbance per minute corrected for blank
Hb = hemolysate hemoglobin concentration in g/100.0 mL

Reference Intervals

Reference intervals for PK are:
High substrate 9 to 22 U/g of Hb
Low substrate 1.7 to 6.8 U/g of Hb

Comments and Precautions

The same precautions need to be taken with this assay as those for the G6PD assay. A normal control must be run concurrently with every specimen assayed.

Method 21-5. Determination of Glucose Phosphate Isomerase Activity

Deficiency of glucose phosphate isomerase (GPI) has been associated with chronic hemolytic disease and may also cause hemolytic disease of the newborn. Although the third most frequently reported enzymopathy causing hemolytic disease, it has been quite rare in our experience.

Principle

As shown below, GPI catalyzes the interconversion of G6P and F6P:

$$\text{F6P} \xrightarrow{GPI} \text{G6P}$$

$$\text{NAPH}^+ + \text{G6P} \xrightarrow{G6PD} \text{6-phosphoguconate} + \text{NAPHD} + \text{H}^+$$

In this assay, F6P is used as the substrate for GPI. The GPI reaction is linked to the G6PD reaction. The rate of reduction of $NADP^+$, as indicated by the increase in absorbance at 340 nm, is the measure of GPI activity.

Reagents

The stock reagent solution for the G6PD assay is also used in assaying GPI activity.

1. Stock reagent solution (see G6PD assay).
2. F6P, 0.02 mol/L, aqueous.
3. G6PD (type XI, crystalline, Sigma Chemical Co.). Dilute in EDTA-mercaptoethanol "hemolyzing solution," described later.
4. EDTA, 10.27 mol/L, pH 7.0. To 100.5 g sodium-EDTA·$2H_2O$ (MW 372.24), add approximately 900 mL distilled water and adjust to pH 7.0 with 0.1 M/L sodium hydroxide (NaOH). Add water and dilute to 1000 mL final volume. This reagent is stable up to 1 year at 4 °C.
5. Stabilizing solution. To 0.25 mL β-mercaptoethanol, add 5.0 mL EDTA, 0.27 mol/L. Adjust pH to 7.0 and dilute to 500 mL with distilled water. This solution is stable for 1 month at 4 °C.

Procedure

1. Thaw the stock reagent solution prepared for G6PD assays or prepare fresh stock reagent solution.
2. Prepare the following 1-mL cuvets (of which No. 1 is the blank for a normal control, No. 2 is the normal control assay, No. 3 is the specimen blank, and No. 4 is the specimen assay).

	Cuvet No.			
Reagents (mL)	**1**	**2**	**3**	**4**
Stock reagent solution	0.880	0.880	0.880	0.880
Water	0.105	0.005	0.105	0.005
F6P, 0.02 mol/L	—	0.100	—	0.100

3. To each cuvet add 0.01 mL of a 10-U/mL suspension of G6PD.
4. Cap and invert twice to mix.
5. Incubate at 37 °C for 1 hour; then add to each cuvet 0.005 mL of hemolysate, prepared as described previously.
6. Cap and invert twice to mix. Then place in spectrophotometer chamber and measure increase in absorbance at 340 nm for at least 10 minutes at 37 °C. Determine ΔA340/min, corrected for ΔA340/min of blank.
7. While the preceding step is being carried out, measure the hemolysate hemoglobin concentration, Hg.
8. Calculate RBC GPI activity in units per gram of hemoglobin

$$\text{GPI}(\text{U}/\text{g Hb}) = \frac{804 \times \Delta A_{340}/\text{min}}{\text{Hb}}$$

Reference Intervals

Reference intervals for GPI are:
60.8 ± 11.0 U/g Hb (mean ± 2 SD)
3.92 ± 0.72 MU/mol Hg (mean ± 2 SD)

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

Comments and Precautions

The same precautions discussed under G6PD assay apply to the GPI assay. There may be an advantage in also assaying at low substrate concentration (0.005 mL instead of 0.1 mL F6P solution in each cuvet) to identify GPI variants with atypical kinetic curves.

Method 21-6. Determination of Erythrocyte Glutathione Concentration

Erythrocyte GSH concentration is diminished in many people who have defects in the hexose monophosphate or GSH synthesis pathways. The GSH stability test, originally devised to permit identification of people susceptible to hemolysis from primaquine (later shown to be the result of G6PD deficiency), still remains a useful "stress test" of the intactness of these closely linked pathways. Because deficiencies of GSH synthetase and γ-glutamyl cysteine synthetase are rare disorders, it is not practical for clinical laboratories to contemplate assays for these enzymes unless results of the easily performed GSH stability test are abnormal.

Principle

Virtually all of the nonprotein sulfhydryl groups of RBCs are in the form of reduced GSH. 5,5′-Dithiobis(2-nitrobenzoic acid) (DTNB) is a disulfide chromogen that is readily reduced by sulfhydryl compounds to an intensely yellow compound. The absorbance of the reduced chromogen is measured at 412 nm and is directly proportional to the GSH concentration.

Specimen Collection

The assay should be conducted on whole blood, 3 mL, anticoagulated with ACD. GSH concentration declines in blood anticoagulated with heparin or EDTA; for such specimens, the assay should be carried out on the same day. Include at least one normal control specimen with each assay.

Reagents

1. Precipitating solution. In a 100-mL volumetric flask, place 1.67 g of glacial metaphosphoric acid, 0.20 g of disodium- or dipotassium-EDTA, and 30.00 g of NaCl, and bring to volume with distilled water. This solution is stable for 3 weeks at 4 °C. A fine precipitate may form owing to EDTA, but this does not interfere with the test.
2. Disodium phosphate solution, 0.3 mol/L. In a 1-L volumetric flask, place 42.59 g of Na_2HPO_4 and bring to volume with distilled water. The solution is stable indefinitely at 4 °C. If crystals form, dissolve by heating.
3. DTNB reagent. In a 100-mL volumetric flask, place 40.0 mg of DTNB (Sigma Chemical Co.). Bring to volume with a solution of sodium citrate, 1 g/dL. This solution is stable for at least 13 weeks at 4 °C.
4. GSH calibrators. Place 100 mg GSH (Sigma Chemical Co.) in a 100-mL volumetric flask and bring to volume with reagent grade water. Invert repeatedly until GSH is completely dissolved. Prepare 50- and 10-mg/dL calibrators by diluting 5 mL of the 100-mg/dL calibrator with 5 and 45 mL, respectively, of reagent grade water. The GSH calibrators are not stable and must be freshly prepared on the day of the assay.

Procedure

1. Place 0.2 mL of whole blood into a 10-mL test tube and add 1.8 mL of distilled water. Mix to hemolyze.
2. Promptly add 3.0 mL of precipitating solution. Mix.
3. Allow to stand 5 minutes at room temperature and then filter through coarse-grade filter paper.
4. Prepare cuvets as follows:

Reagent (mL)	Blank	Assay
Filtrate	—	2.0
Precipitating reagent	1.2	—
Water	0.8	—
Na_2HPO_4 solution	8.0	8.0
DTNB solution	1.0	1.0

5. Cap cuvets and invert three times to mix.
6. Read absorbance at 412 nm within 4 minutes of preparing cuvets.
7. Obtain hematocrit of original whole-blood specimen.
8. Assay GSH calibration, omitting filtration step.
9. Prepare a calibrator curve. Determine the GSH concentration of the blood specimen from the graph.
10. Calculate GSH concentration

$$\text{GSH}(\text{mg}/\text{dL of RBCs}) = \frac{\text{GSH conc. (from calibration curve)}}{\text{Hematocrit}}$$

Reference Interval

The reference interval for GSH is 202 ± 22 μmol/10^{12} RBCs (202 ± 22 amol/RBC).

Comments and Precautions

The ability of RBCs to maintain a normal GSH concentration when stressed by an oxidant substance may be tested by

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

incubation of blood with 1-acetyl-2-phenylhydrazine and glucose for 2 hours at 37 °C. In this GSH stability test, GSH concentration is measured before and after incubation of blood with 1-acetyl-2-phenylhydrazine. RBCs deficient in G6PD, GSH-S, or γ-glutamyl cysteine synthetase exhibit a marked decrease in GSH concentration after such stress. Details of this test are given in the first reference cited below.

Method 21-7. Screening for Deficiency of Pyrimidine-5′-Nucleotidase Activity

Principle

Pyrimidine-5′-nucleotidase effects the release of phosphate from cytidine-5′-monophosphate and uridine-5′-monophosphate and thus is an enzyme involved in the catabolism of RNA. RNA is a normal constituent of reticulocytes but not of mature RBCs. In the absence (or marked deficiency) of P-5′-N, RNA persists in RBCs and is manifested by striking basophilic stippling and mild to moderate hemolytic anemia.

Pyrimidine nucleotides, extracted with acid from the RNA remaining in P-5′-N–deficient RBCs, have an absorption peak at 270 nm. This peak is quite distinct from the peak at 257 nm that is due to purine nucleotides (such as ATP), which are normally present. When P-5′-N is deficient and RNA persists, the P-5′-N deficiency can be inferred by observing a pyrimidine nucleotide peak at 270 nm in an acid extract of RBCs.

Specimen Collection

A minimum of 1 mL of whole blood anticoagulated with EDTA or ACD is required. Include at least one normal specimen as a control. A solution of cytidine-5′-monophosphate, 3 mmol/L, may be used as a simulated abnormal control. (Because of the rarity of this disorder, true abnormal controls are usually not available.)

Reagents

1. Perchloric acid (PCA), 0.6 mol/L.
2. Cytidine-5′-monophosphoric acid (Sigma Chemical Co.), 3.0 mmol/L (aqueous).

Procedure

1. Centrifuge blood at 1500 × *g* for 10 minutes; remove and discard supernatant plasma.
2. Resuspend RBCs in NaCl, 0.155 mol/L. Centrifuge at 1500 × *g* for 10 minutes.
3. Remove and discard the supernatant.
4. Repeat steps 2 and 3.
5. To 0.5 mL of washed, packed RBCs add 0.5 mL of PCA, 0.6 mol/L. Mix thoroughly.
6. Centrifuge at 1500 × *g* for 20 minutes.
7. Carefully transfer the supernatant to another tube. From this, pipette 0.3 mL to a UV cuvet of 4-mL maximum volume. Add 2.7 mL of PCA, 0.6 mol/L, to this (sample) cuvet, and 3 mL of PCA, 0.6 mol/L, to a second (blank) cuvet. Use 0.3 mL of reagent 2, plus 2.7 mL of PCA, 0.6 mol/L, for abnormal control.
8. Determine absorbance in the wavelength range of 240 to 290 nm either by scanning or at 5-nm intervals and at 257 nm. Plot the absorbance curve or alternatively scan with a recording spectrophotometer.

Reference Intervals

In normal specimens or in those of any disorder but P-5′-N deficiency, there is an absorbance curve of low amplitude with a peak at about 257 nm, this being due to the presence of purines such as ATP and ADP. No peak is seen at 270 nm. In P-5′-N deficiency, a notably higher-amplitude curve is observed, with a peak at 270 nm. The absorbance maximum for normal RBCs is 257 nm, and the observed absorbance value is approximately 0.3/108 RBCs per milliliter. In P-5′-N deficiency, the peak absorbance is at 270 nm, with absorbance values of approximately 0.8/108 RBCs per milliliter having been observed. No interfering substances are known.

Comments and Precautions

As far as is known, all cases of P-5′-N deficiency have given positive results with this test. False-positive results have not been observed. This is not a reliable test for lead poisoning. PCA is explosive, and must be handled and stored with care.

Method 21-8. Determination of 2,3-Diphosphoglycerate in Erythrocytes

This enzyme is the predominant glycolytic intermediate of RBCs and has a vital role in modulating the affinity of hemoglobin for O_2.

Principle

The assay of 2,3-DPG is based on an equilibrium system between 3-phosphoglycerate, 2-phosphoglycerate, and PEP when monophosphoglycerate mutase (MPGM) and enolase are present.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

The addition of 2,3-DPG (in the sample) shifts the equilibrium so that more 2-phosphoglycerate is converted to 3-phosphoglycerate. This in turn results in the conversion of PEP to 2-phosphoglycerate. The rate of decrease in PEP concentration is measured by the decrease in absorbance at 240 nm, which is proportional to the amount of 2,3-DPG in the specimen.

Specimen Collection

Add two drops of whole blood to 2 mL of ice-cold distilled water immediately from the syringe tip. Mix to hemolyze. The specimen must arrive in the laboratory packed in ice (0 °C to 4 °C). Because 2,3-DPG concentration declines rapidly once blood is drawn, it is critical that blood for this assay be lysed and chilled immediately. This is best done by drawing blood with a syringe and transferring the specimen immediately from the syringe tip to water at 0 °C to 4 °C.

Reagents

1. Stock reagents
   a. TRIS-HCl buffer, 2 mol/L, pH 7.4.
   b. $MgCl_2$, 0.5 mol/L.
   c. EDTA, disodium salt, 0.27 mol/L, pH 7.0. Place 0.27 mol (90.78 g/L) of disodium-EDTA in a 2-L beaker. Add approximately 800 mL of water. Add NaOH, 0.1 mol/L drop by drop, until pH is 7.0. Then transfer to a 1-L volumetric flask and bring to volume with distilled water.
   d. Bovine serum albumin, 35 g/dL.
   e. MPGM suspension (may be purchased as phosphoglycerate mutase, crystalline suspension, 5000 U/mL, from Sigma Chemical Co.).
   f. Enolase suspension (Sigma Chemical Co.).
   g. 2,3-DPG calibrator, 1 mmol/L in distilled water. This solution is stable for several months if stored at −20 °C.
2. Working reagent solution (prepare daily and store at 4 °C until used).
   a. Dilute bovine serum albumin to 0.5 g/dL. (Add 1 mL to 69 mL of distilled water.)
   b. Dilute enolase in distilled water to approximately 32 U/mL.
   c. Dilute MPGM suspension in distilled water to approximately 1600 U/mL.
   d. Prepare PEP solution, 0.25 mol/L.
   e. Mix the following to prepare working reagent solution: 0.4 mL TRIS-HCl buffer; 0.2 mL $MgCl_2$ solution; 0.6 mL PEP solution; 0.2 mL EDTA solution; 0.2 mL MPGM (diluted); 0.2 mL enolase (diluted); 1.8 mL bovine serum albumin (diluted); and 14.4 mL deionized water, for a total volume of 18.0 mL.
3. Dilute TRIS-HCl buffer. On the day of the assay, add 1 mL of the stock TRIS-HCl buffer to 99 mL of distilled water. Mix.
4. 2,3-DPG calibrators, 1.0 µmol/L. Thaw stock 2,3-DPG calibrator and dilute 1000-fold by adding 0.1 mL to 99.9 mL of dilute TRIS-HCl buffer. Make further dilutions as shown:

Final 2,3-DPG Calibrator Concentration (µmol/L)	2,3-DPG Calibrator 1 µmol/L (mL)	TRIS-HCl (mL)
0	0.0	1.0
0.25	0.4	1.2
0.50	0.8	0.8
0.75	1.2	0.4
1.00	1.0	0.0

Procedure

1. Transfer 0.02 mL of hemolysate to 2 mL of dilute TRIS-HCl buffer, pH 7.4.
2. Add 0.9 mL of working reagent solution to cuvets with 1-mL critical volume, preparing one cuvet as a blank for calibrator, and samples. Allow to warm to room temperature for at least 10 minutes.
3. Add to the blank cuvet 0.1 mL of distilled water; add 0.1 mL of the 0-, 0.25-, and 0.50-µmol/L calibrators to the respective cuvets. Mix by inversion and measure the absorbance change at 240 nm for 10 minutes at 25 °C.
4. Add 0.1 mL of the 75- and 100-µmol/L calibrators to respective cuvets and 0.1 mL of diluted hemolysate to the sample cuvets. Mix by inversion and measure the absorbance change at 240 nm for a 10-minute interval at 25 °C. Plot ΔA_{240}/min against the concentration on a graph for calibration curve.
5. Using the ΔA_{240}/min calculated for each specimen, find on the calibration curve the corresponding concentration of 2,3-DPG. Designate this concentration C_c.
6. Measure the Hb concentration of each hemolysate. Add 0.5 mL of the original hemolysate to 2.5 mL of Drabkin's solution. Mix. Determine A_{540nm} of the cyanmethemoglobin calibrator (80 mg/dL) and of each hemolysate.

Calculations

$$C_{Hb}(mg/dL) = 6 \times 80 \times \frac{A_{540}(\text{hemolysate})}{A_{540}(\text{calibrator})}$$

$$C_{Hb}(g/L) = C_{Hb}(mg/dL) \times \frac{10}{1000}$$

$$C_{2,3\text{–}DPG}(\text{mmol/g Hb}) = \frac{100 \times C_C}{C_{Hb}(g/L)}$$

where

C_{Hb} = hemoglobin concentration of the hemolysate
6 = dilution of the hemolysate
80 = concentration of the cyanmethemoglobin (mg/L)
100 = dilution of the hemolysate
10 = conversion from dL to L
1000 = conversion of mg to g

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

C_c = concentration of 2,3-DPG (μmol/L read from the calibration curve)

Reference Intervals

The reference intervals for 2,3-DPG are 12.3 ± 1.87 μmol/g Hb (0.79 ± 0.12 mol/mol Hb [mean ± 1 SD]) or 356 ± 54 μmol/1012 RBCs (356 ± 54 amol/RBC [mean ± 1 SD]).

Comments and Precautions

If the assay is not to be performed on the same day, measure the hemolysate hemoglobin concentration of a small aliquot and heat the remainder for 10 minutes in a boiling water bath to inactivate phosphatases. Freeze the boiled hemolysate and keep it frozen until ready to assay.

METHOD FOR THE MEASUREMENT OF INSULIN

Principle

The principle and general procedures of RIA are described elsewhere (see Chapter 9). ^{125}I-labeled insulin competes with insulin in a patient sample for binding to an insulin-specific antibody immobilized on the walls of a polypropylene tube. The supernatant is decanted, and the bound ^{125}I determined in a gamma counter. The amount of insulin in the sample is established by comparison with a calibration curve obtained by plotting on logit-log graph paper the percent of total radioactivity bound (B/T%) against the concentration of the calibrators. Various commercial kits for insulin measurement are now available.

Specimen Collection and Storage

No special specimen preparation is required for collection of blood samples. Insulin may be measured in serum or plasma from a fasting patient. If analysis is performed with plasma, heparin should be used because ethylenediaminetetraacetic acid (EDTA) spuriously increases values in the most commonly used assays. The effects of different blood collection tubes on different methods are not well documented. Users should refer to the manufacturer's data sheet for commercially available assays. Hemolysis can significantly lower insulin values. Insulin is stable in whole blood at room temperature for at least 5 hours. Samples may be stored at 4 °C for 7 days or at −20 °C for as long as 3 months; repeated thawing and freezing should generally be avoided, although this may be acceptable with some assays.

Urine and cerebrospinal fluid (CSF) may be assayed for insulin content. These samples require an extraction step and concentration before analysis.

Reagents

1. Insulin antibody-coated tubes. When stored refrigerated and protected from moisture, these remain stable for 1 year at 4 °C.
2. ^{125}I-insulin, buffered. Reconstitute with 100 mL distilled or deionized water, let stand for 10 minutes, and mix by inversion. Stability is 1 month at 4 °C.
3. Calibrators—0, 5, 15, 50, 100, 200, 400 µIU/mL insulin in lyophilized processed human serum. The zero calibrator (B_0 or maximum binding) is reconstituted with 6 mL of distilled water. Reconstitute all other calibrators with 3 mL of distilled water. Stability is 1 month at −20 °C after reconstitution.

Procedure

Bring all reagents, calibrators, and specimens to room temperature. All calibrators and specimens are prepared in duplicate.

1. Label two uncoated 12- × 75-mm polypropylene tubes *T* (total counts) and two *NSB* (nonspecific binding).
2. Label two coated tubes each for B_0 (maximum binding), calibrators, and patient's specimens.
3. Add 200 µL of calibrator and specimen to the labeled tubes. Pipette directly to the bottom of the tube.
4. Add 1.0 mL ^{125}I-insulin to each tube; vortex briefly and gently. This step should be performed with minimal delay. The tubes for total counts require no further processing and may be set aside.
5. Incubate all tubes for 18 to 24 hours at room temperature or for 3 hours in a 37 °C water bath.
6. Decant thoroughly and allow to drain for 2 to 3 minutes. Removing all visible moisture significantly enhances precision.
7. Count for 1 minute in a gamma counter.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

Calculations

For each pair of tubes, determine the corrected counts per minute (cpm).

$$\text{Corrected cpm} = \text{average cpm} - \text{average NSB}$$

$$\text{Maximum binding } (B_0) = \text{average cpm } B_0 - \text{NSB}$$

$$\text{Percent bound} = \frac{\text{sample cpm}}{B_0} \times 100$$

Plot data for calibrators on a logit-log graph—*percent bound* on the vertical axis against *concentration* on the horizontal axis. Insulin concentrations for the unknowns are estimated from the calibration curve by interpolation. Alternatively, online data reduction may be performed with commercially available software (e.g., COBRA RIA Smart software or IBM/AT RIA Aid software)

2. Andersen L, Dinesen B, Jorgensen PN, Poulsen F, Roder ME. Enzyme immunoassay for intact human insulin in serum or plasma. Clin Chem 1993;39:578-82.

Comments

1. The term *immunoreactive insulin* is used in reference to assays that may recognize, in addition to insulin, substrates that share antigenic epitopes with insulin. Examples include proinsulin, proinsulin conversion intermediates, and insulin derivatives produced by glycation or dimerization.
2. Various insulin preparations, including human insulin, are used as insulin calibrators. For ease of comparison of results among laboratories, the insulin calibrator is expressed in terms of international units (IU). One international unit of insulin is equal to approximately 43 μg of the World Health Organization (WHO) first International Reference Preparation (1st IRP) Code 66/304 (National Institute of Biological Standards and Control, South Mimms, Potters Bar, Hertfordshire, United Kingdom), which is 100% human insulin.
3. *Antisera raised against insulin show some cross-reactivity with proinsulin but not with C-peptide.* Specificity is not a problem in healthy individuals because the low proinsulin concentrations do not appreciably affect the absolute values of insulin. In certain situations (e.g., islet cell tumors and diabetic individuals), proinsulin is present at higher concentrations and direct assay of plasma may falsely overestimate the true insulin concentration. Because proinsulin has very low activity, incorrect conclusions regarding the availability of biologically active insulin may be reached in patients with diabetes. The magnitude of the error depends on the concentration of proinsulin and the extent of cross-reactivity of the antiserum with proinsulin. Monoclonal antibodies that are specific for insulin and do not measure proinsulin, although theoretically advantageous, are not superior to nonspecific assays.
4. A stable isotope dilution assay using mass spectrometry to measure insulin, proinsulin, and C-peptide has been developed. The difference in mass among the three analytes allows specific measurement of each protein. Comparison of patient samples revealed that most, but not all, results were higher by immunoassay than mass spectrometry. Thus immunoassays may overestimate insulin, particularly at low concentrations. The high protein concentration in the serum requires extraction of proteins (e.g., by immunoaffinity) and purification by HPLC before quantification by mass spectrometry. This method is not suitable for routine laboratory analysis.
5. The American Diabetes Association (ADA) appointed a task force to standardize the insulin assay. Evaluation of unknown samples by 17 different laboratories revealed a wide range in insulin values, with interlaboratory variance of up to threefold. Large differences were observed even among laboratories using the same assays. Use of a common calibrator did not improve variance among laboratories. Assay coefficients of variation (CVs) ranged from <2% to >30%, with ELISAs exhibiting the lowest imprecision. Certain characteristics of some assays, including commercial kits, were unacceptable. The task force judged available proficiency and certification programs for insulin to be inadequate and recommended the establishment of a central laboratory to provide certification for insulin assays. Complete interlaboratory standardization was deemed to be neither practical nor universally acceptable. The ADA recommendations for analysis of insulin are as follows:
   a. Each laboratory should carefully evaluate its insulin assay to ensure acceptable assay performance.
   b. Each laboratory should compare the performance of its assay with others using common calibrators and unknown samples.
   c. Because assay performance may change with time or with new reagents or equipment, performance characteristics must be remeasured periodically.
6. Acceptance criteria for an insulin assay are <15% interassay CV. Minimal detectable amount of insulin, as calculated from the calibration curve, should be 1 μIU/mL with the overnight procedure or 3 μIU/mL with the same-day procedure. In addition, recovery and linearity should be ±15%, and the in-house insulin calibrator should be within 5% of the gold standard. No gold standard was specified.
7. Patient samples with high values should be diluted with the zero calibrator.
8. The presence of antibodies to insulin results in spuriously increased or decreased (depending on the method used) insulin values.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

Reference Intervals

These vary among assays and each laboratory should establish its own reference intervals. After an overnight fast, insulin concentrations in healthy, normal, nonobese people range from 2 to 25 μIU/mL (12 to 150 pmol/L). More specific assays that have minimal cross-reactivity with proinsulin reveal a fasting plasma insulin concentration of <9 μIU/mL (60 pmol/L). Concentrations up to 200 μIU/mL can be reached during a glucose tolerance test. Fasting insulin values are higher in obese, nondiabetic people and lower in trained athletes.

METHODS FOR THE MEASUREMENT OF INSULIN ANTIBODIES

Assays for insulin antibodies fall into three categories: (1) quantitative radioimmunoelectrophoresis, which measures the binding of IgG antibody to radiolabeled insulin by rocket immunoelectrophoresis into anti–IgG-containing agarose; (2) RIAs with separation of bound and free insulin by precipitation with PEG or a second antibody; and (3) solid-phase immobilization of insulin to test tubes or Sepharose.

METHOD FOR THE MEASUREMENT OF PROINSULIN

Principle

Accurate measurement of proinsulin has been difficult for several reasons: the blood concentrations are low; antibody production is difficult; most antisera cross-react with insulin and C-peptide, which are present in much higher concentrations; the assays measure intermediate cleavage forms of proinsulin; and reference preparations of pure proinsulin were not readily available. Therefore few accurate data are available in the literature on plasma proinsulin. These problems have, to a large extent, been overcome by the availability of biosynthetic proinsulin, which has allowed the production of monoclonal antibodies to proinsulin and provided reliable proinsulin calibrators and reference preparations. An International Reference Preparation for human proinsulin (code 84/611) is available from the National Institute of Biological Standards and Controls (Potters Bar, UK). Earlier assays may have overestimated proinsulin concentrations.

SPECIMEN COLLECTION AND STORAGE

Fasting blood samples should be collected in heparinized tubes. Plasma is stable at −20 °C or −70 °C for at least 3 months.

Procedure

Because the proinsulin molecule contains both insulin and C-peptide, antisera to proinsulin were not specific. Over the years, a number of different approaches have been used to measure proinsulin. These usually involved preliminary separation procedures that were time consuming and labor intensive. Moreover, most assays did not achieve adequate sensitivity to reliably measure proinsulin levels in healthy, fasting subjects. Specific antibodies to proinsulin and a variety of complementary antibody assays have improved the sensitivity, specificity, and accuracy of proinsulin measurement. The techniques available to measure proinsulin are briefly outlined next.

Separation

1. Removal of C-peptide. Anti-insulin antiserum bound to a solid phase (e.g., polyethylene tubes or Sepharose) separates insulin and proinsulin (which bind) from C-peptide. After the C-peptide is washed away, proinsulin is measured in a C-peptide assay that does not cross-react with insulin. This method is reported to result in higher immunoreactivity of intermediate cleavage forms of proinsulin than the intact molecule.
2. Removal of insulin. This approach uses an anti-insulin antibody to measure proinsulin after removal of insulin from the sample. Preliminary separation of insulin can be achieved by (1) chromatography (e.g., Biogel P-30 or Sephadex G-50); (2) incubating plasma or serum with an insulin-specific protease that degrades insulin into nonimmunoreactive products; or (3) immunoprecipitation. In the last method, proinsulin and C-peptide are immunoprecipitated from plasma with an antiserum to C-peptide. The pellet is washed to remove insulin (which does not bind) and proinsulin is dissociated from the antibody with warm HCl. The eluted material is assayed in an insulin RIA, with human proinsulin as the calibrator.
3. High-performance liquid chromatography (HPLC). HPLC is capable of resolving insulin, proinsulin, and individual proinsulin conversion products, but the procedure is complex, labor intensive, and requires extraction steps.

Specific Proinsulin Antibodies

1. Polyclonal. Antibodies against either the insulin/C-peptide junction or proinsulin were produced initially. These assays require concentration of plasma or an extraction process before measurement to achieve adequate assay sensitivity. A more sensitive nonequilibrium RIA was developed by adsorbing the initial antiserum with biosynthetic human C-peptide–agarose to eliminate cross-reactivity with C-peptide. In another approach, a polyclonal antibody to proinsulin was captured on microtiter plates and a sandwich was formed with an enzyme-labeled monoclonal antibody against C-peptide. This assay exhibits a detection limit for proinsulin of 0.1 pmol/L.
2. Monoclonal. Specific antibodies to proinsulin that do not cross-react with insulin have been developed. The use of these antibodies, coupled with a purified proinsulin calibrator, should allow direct, more accurate proinsulin measurements. Even this assay, however, does not discriminate between split proinsulins, and the assay sensi-

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

tivity is barely adequate for fasting normal subjects. An ELISA has been described that uses an antibody to C-peptide as the coating antibody and antiinsulin antibody for detection. The detection limit is 0.25 pmol/L.

Reference Intervals

The reference intervals are highly dependent on the method of analysis, the degree of cross-reactivity of the antisera, and the purity of proinsulin calibrators. Each laboratory should establish its own reference intervals.

Reference intervals in healthy, fasting individuals reported in the literature range from 1.1 to 6.9 pmol/L to 2.1 to 12.6 pmol/L.

METHOD FOR THE MEASURMENT OF C-PEPTIDE

Principle

C-peptide provides the advantages of undergoing minimal liver metabolism and, in contrast to proinsulin, assays do not react with anti-insulin antibodies. However, various methodological problems produce large between-method variation. These difficulties include variable specificity among different antisera, variable cross-reactivity with proinsulin, and the type of C-peptide preparation used as a calibrator. A comparison, in the clinically relevant range, using four commercial kits and four commercial C-peptide antisera yielded values ranging from 0.54 to 1.06 nmol/L on the same sample. Furthermore, a tyrosine residue must be incorporated onto the C-peptide to enable labeling with ^{125}I. Several immunometric methods have been described for the measurement of C-peptide, and a number of kits are commercially available. A brief outline of the RIA methodology follows.

Specimen Collection and Storage

C-peptide is less stable than insulin and proinsulin. The effects of time of storage and freeze/thaw cycles are dependent on the assay used. Serum samples are stable for 3 months at −20 °C.

Procedure

The antiserum is raised in rabbits, guinea pigs, or goats against a conjugated synthetic human C-peptide analogue. A similar ^{125}I-labeled analogue serves as the radioactive ligand. Patients' samples and human C-peptide calibrators are incubated overnight at 4 °C with an equal volume of diluted antiserum. The radioactive label is added, and after further incubation, the antigen-antibody complex is precipitated by adding a second antibody and PEG. After centrifugation at 4 °C for 20 minutes at 800 ×*g* to separate bound from free label, the supernatant fluid is decanted and ^{125}I in the precipitate is quantified in a gamma counter.

The reliability criteria are comparable to those for the insulin assay. The RIA can detect as little as 75 pg/mL, and insulin does not cross-react in this assay. In samples from insulin-treated patients, however, precipitation of insulin antibodies and insulin antibody-proinsulin complexes with PEG before assay for C-peptide is often recommended.

Reference Intervals

Each laboratory should establish its own reference interval. Fasting serum concentrations of C-peptide in healthy people range from 0.78 to 1.89 ng/mL (0.25 to 0.6 nmol/L). After stimulation with glucose or glucagon, values range from 2.73 to 5.64 ng/mL (0.9 to 1.87 nmol/L), three to five times the prestimulation value. Urinary C-peptide is usually in the range of 74 ± 26 µg/L (25 ± 8.8 µmol/L). C-peptide is excreted predominantly by the kidney, and concentrations in the serum are increased in renal disease.

METHOD FOR THE MEASUREMENT OF GLUCAGON

Principle

A competitive RIA is available for measuring glucagon (Diagnostic Products Corp.). ^{125}I-labeled glucagon competes with glucagon in the patient specimen for binding to polyclonal glucagon antibody. Bound glucagon is separated from free using PEG and a second antibody. Bound radioactivity for the patient specimen is compared with that of glucagon calibrators. The calibrator values are assigned at the manufacturer using the WHO glucagon International Standard (69/194).

Specimen Collection and Storage

Fasting blood samples should be collected in chilled EDTA tubes. Glucagon is very unstable in blood. Immerse tubes in a 2 °C to 8 °C ice-water bath. Immediately add a proteolytic inhibitor such as Trasylol (200 µL per 4 mL blood; approximately 2000 kallikrein-inactivating units). Separate plasma from cells in a refrigerated centrifuge at 4 °C. Freeze at least 1 mL of plasma at −20 °C and avoid exposure to light. Thaw just before testing.

Procedure

1. Label 12 × 75 mm glass tubes (glucagon binds to some types of plastic) in duplicate for each calibrator (25, 50, 100, 250, 500, and 1000 ng/L), nonspecific binding (NSB), B_0 (maximum binding), total counts, controls, and specimens.
2. Add 200 µL of each calibrator, control, and specimen to the appropriate tubes.
3. Add 100 µL glucagon rabbit antiserum to each tube except the NSB and total tubes.
4. Mix using a vortex, cover with parafilm, and incubate for 24 hours at 4 °C.
5. Add 100 µL of ^{125}I-glucagon to all tubes and mix well with a vortex. Set aside the total tubes without further processing. Cover the remaining tubes with parafilm and incubate for 24 hours at 4 °C.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

6. Add 1.0 mL of precipitating solution consisting of goat antirabbit gamma globulin and dilute with PEG at 4 °C to each. Mix well and centrifuge at 1500 ×*g* for 15 minutes at 4 °C.
7. Decant supernatant fluid completely and count each tube for 1 minute in a gamma counter.
8. Subtract the average NSB counts from each of the other count averages. Divide all corrected counts by the average corrected counts for B_0. Plot the percent bound versus calibrator concentration using log-logit coordinates. The calibration curve should be straight.
9. Report values from 25 to 1000 ng/L (35 to 290 pmol/L). Dilute specimens greater than 1000 ng/L with zero calibrator and retest.

Reference Intervals

Fasting plasma concentrations of glucagon vary from 70 to 180 ng/L (20 to 52 pmol/L). Values up to 500 times the upper reference limit may be found in patients with autonomously secreting α-cell neoplasms.

GLUCOSE OXIDASE PHOTOMETRIC METHOD FOR GLUCOSE

This photometric method may be applied to plasma, serum, whole blood, or CSF. It should not be used for urine because of the high concentration of enzyme inhibitors present. Deproteinated filtrates should be used for whole blood and for serum or plasma that is appreciably hemolyzed, icteric, or lipemic. Heparin, oxalate, and EDTA are satisfactory anticoagulants. NaF (2.5 mg/mL of blood) may be used as a preservative, but not thymol, which inhibits the enzyme reaction.

This procedure is based on that of Raabo and Terkildsen and modified for optional use with deproteinated filtrates. Reagents may be obtained separately or in kit form (Sigma Chemical Co., St. Louis).

Reagents

1. $ZnSO_4$ solution, 0.17 mol/L. Dissolve 50 g of $ZnSO_4 \cdot 7H_2O$ in water and dilute to 1 L.
2. $Ba(OH)_2$ solution, approximately 0.15 mol/L. Dissolve 50 g of $Ba(OH)_2 \cdot 8H_2O$ in water and dilute to 1 L. Let stand for 2 days in a covered container, then decant or filter. Store in a polyethylene bottle and protect from carbon dioxide in the air. This solution must be neutralized with $ZnSO_4$ as follows: pipette 10.0 mL of the $ZnSO_4$ solution into a flask and dilute with 25 mL of water. Add two drops of 1% phenolphthalein and titrate slowly with the $Ba(OH)_2$ solution, using vigorous mixing, to a definite permanent pink color. Dilute the stronger of the two reagents, if necessary, such that 10.0 mL of $ZnSO_4$ solution requires 10.0 ± 0.1 mL of $Ba(OH)_2$ solution for neutralization.
3. Phosphate buffer, 67 mmol/L, pH 7.0. Dissolve 5.81 g of anhydrous sodium phosphate (dibasic) (Na_2HPO_4) and 3.55 g of potassium phosphate (monobasic) (KH_2PO_4) in water and dilute to 1 L. Store in a polyethylene bottle at room temperature. The pH of the buffer is not critical because the color development in the procedure has a rather wide pH optimum of 6.5 to 8.0.
4. Enzyme solution. This reagent is prepared to contain 500 IU of glucose oxidase *(Aspergillus niger)* and 100 Purpurogallin units of peroxidase (horseradish) in 100 mL of phosphate buffer. The enzyme units are those defined by Sigma. Preweighed capsules containing the enzymes and buffer salts are available. This solution is stable for 1 month at 4 °C and 6 months at −20 °C.
5. *o*-Dianisidine reagent. Dissolve 50 mg of *o*-dianisidine dihydrochloride in 20 mL of water. This reagent is stable for 3 months in a brown bottle at 4 °C.
6. Working reagent. Add 1.6 mL of *o*-dianisidine reagent to 100 mL of enzyme solution. The working reagent is stable up to 1 month at 4 °C.
7. Benzoic acid solution, 1 g/L. Dissolve 1 g of benzoic acid in water, with gentle warming, and dilute to 1 L.
8. Stock glucose calibrator, 1 g/dL. Transfer 1.0 g of dry reagent grade glucose to a 100-mL volumetric flask. Add approximately 60 mL of benzoic acid solution, mix to dissolve, then dilute to the mark with benzoic acid solution. Mix thoroughly and store in a tightly stoppered bottle at 4 °C. This solution is stable indefinitely if kept from evaporation because of the bacteriostatic effect of benzoic acid. Calibrating solutions prepared from dry glucose should stand at least 2 hours to ensure that mutarotation has reached a state of equilibrium.
9. Working glucose calibrator, 100 mg/dL. Allow a portion of the stock calibrator to reach room temperature. Pipette 10.0 mL of the stock calibrator into a 100-mL volumetric flask and dilute to the mark with benzoic acid solution. Additional working calibrators may be prepared by suitable dilution of the stock calibrator.

Procedure Using the Direct Reaction

1. Pipette 25 µL of working calibrator, serum, plasma, or CSF into respective test tubes.
2. Add 0.5 mL of water to each tube and to a separate tube for a reagent blank. Note: Alternatively, 0.5 mL of a 1 : 20 aqueous dilution of calibrators and samples may be used.
3. Add 5.0 mL of working reagent to each tube and mix.
4. Incubate all tubes at 37 °C for 30 minutes or at room temperature for 45 minutes. The color is now fully developed. Avoid exposing the tubes to direct sunlight during incubation.
5. Measure absorbance at 500 nm within the next 30 minutes against the reagent blank.

$$\frac{A_{sample}}{A_{calibrator}} \times 100\ \text{mg/dL calibrator} = \text{milligrams of glucose per deciliter of sample}$$

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

6. If the test result is greater than 300 mg/dL, dilute the original specimen twofold or fourfold with water and repeat the assay, including the calibrator and reagent blank. Multiply the result by 2 or 4, depending on the dilution.

Procedure Using Deproteinated Samples

1. Pipette 0.20 mL of working calibrator and samples into respective test tubes.
2. Add 1.8 mL of water to each.
3. Pipette 2.0 mL of water into a separate tube for a reagent blank.
4. Add 1.0 mL of $Ba(OH)_2$ solution to each tube and mix.
5. Add 1.0 mL of $ZnSO_4$ solution to each tube and mix well.
6. Centrifuge to obtain a clear supernatant.
7. Transfer 0.5 mL of supernatant from each tube to corresponding test tubes.
8. Proceed as described under the direct procedure, starting with step No. 3.

Comments

1. The absorbance is usually linear with glucose concentrations up to 300 mg/dL; however, linearity should be checked with each new lot of reagent, using calibrators of 100, 200, and 300 mg/dL.
2. A new reagent blank must be prepared for each series of tests because the color of the blank gradually increases with time.
3. If glassware becomes stained by the reagent, the stain may be removed by rinsing with acetone or detergent, followed by water.
4. Rubber tubing used for dispensing solutions has been found to interfere with adequate color development; therefore, rubber tubing connections on dispensers and automatic sampling or diluting devices should be kept to a minimum and should be suspected if calibrators yield unexpectedly low absorbance values.
5. The effect of interfering substances can be minimized by diluting the plasma with an excess of reagents.
6. This procedure is accurate to as low as 25 mg/dL. Accuracy at low levels may be enhanced by performing assays in duplicate.

GLUCOSE DEHYDROGENASE METHOD FOR GLUCOSE

Principle

The enzyme glucose dehydrogenase (β-D-glucose:NAD oxidoreductase, EC 1.1.1.47) catalyzes the oxidation of glucose to gluconolactone. Mutarotase is added to shorten the time necessary to reach equilibrium. The amount of NADH generated is proportional to the glucose concentration.

Glucose dehydrogenase for this assay is isolated from *Bacillus cereus.* The reaction appears to be highly specific for glucose, shows no interference from common anticoagulants and substances normally found in serum, and provides results in close agreement with hexokinase procedures. Methods have been adapted to continuous-flow analyzers, including the use of immobilized enzyme, and to a centrifugal analyzer. The glucose dehydrogenase procedure is not widely used in the United States. A manual kinetic procedure has been described; details can be found in the first edition of this book. The procedure described next is based largely on a kit marketed as UltraChem Gluc-DH by EM Diagnostics Systems (Gibbstown, N.J.; product No. 65048/93.R7050D, issued March, 1985).

Reagents

1. Buffer. The buffer contains 0.12 mol/L phosphate, 0.15 mol/L sodium chloride (NaCl), and 1.0 g/L sodium azide, adjusted to pH 7.6 at 25 °C. It is supplied in bottles containing 100 mL of buffer.
2. Enzyme-coenzyme mixture. This lyophilized mixture, when reconstituted, provides at least 4500 U/L of glucose dehydrogenase, at least 90 U/L of mutarotase, and 2.2 mmol/L of NAD. One unit of glucose dehydrogenase catalyzes the oxidation of 1 μmol of substrate per minute at pH 7.6 and 25 °C. One unit of mutarotase catalyzes the mutarotation of 1 μmol of β-D-glucose per minute at pH 7.2 and 25 °C.
3. Working reagent. Transfer a portion of buffer from one bottle to the vial of enzyme mixture and allow to stand for 15 minutes with occasional swirling. Quantitatively transfer the contents of the vial to the bottle of buffer to supply 100 mL of working reagent. The reconstituted reagent is stable for 12 weeks at 2 °C to 8 °C or up to 4 weeks at room temperature. Absorbance of the reagent greater than 0.4 A (10-mm light path against water) at 340 nm indicates decomposition.
4. Stock glucose calibrator, 1 g/dL (refer to #8 under Reagents under Standard Glucose Oxidase Photometric Method for Glucose).
5. Working calibrator, 200 mg/dL. Warm a portion of the stock calibrator to room temperature. Pipette 20.0 mL of stock calibrator into a 100-mL volumetric flask and dilute to the mark with benzoic acid solution. Additional working calibrators may be prepared by suitable dilution of the stock calibrator.

Procedure

A spectrophotometer capable of measuring absorbance at 340 nm is required. Cuvets should have a 10-mm light path and permit measurements of 2 mL of solution. The procedure may be applied to serum, plasma, urine, or CSF.

1. Label cuvets or test tubes for reagent blank, calibrator, and sample.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

2. Pipette 2.0 mL of working reagent into each cuvet.
3. Pipette 10 µL of water into the blank cuvet and 10 µL of each sample or calibrator into the appropriate cuvets. Mix thoroughly by inversion or on a vortex mixer.
4. Incubate all cuvets in a constant temperature bath or at room temperature for the appropriate time. Recommended times are as follows:

Temperature (°C)	20	25	30	37
Reaction time (min)	10	8	7	7

5. Remove the cuvets after incubation, tap gently to remove bubbles, and wipe dry.
6. Set the spectrophotometer with the reagent blank to zero absorbance at 340 nm. Measure the absorbance of the calibrator and sample.

$$\frac{A_{sample}}{A_{calibrator}} \times 200\ mg/dL\ calibrator = \text{milligrams of glucose per deciliter of sample}$$

COMMENTS

1. Absorbance is usually linear with glucose concentrations up to 1000 mg/dL; however, linearity should be checked using calibrators of both 200 and 1000 mg/dL with each new lot of reagent. When the sample glucose concentration is too high for accurate measurement, dilute the sample twofold with saline (NaCl, 9 g/L) and repeat the analysis.
2. Lipemia interferes by contributing to the absorbance reading at 340 nm. Set up a sample blank by adding 10 µL of serum or plasma to 2.0 mL of saline. Measure absorbance against saline and subtract this value from the observed absorbance for the unknown in the test cuvet before making calculations.
3. Anticoagulants or preservatives reported not to interfere at usual concentrations include heparin, EDTA, citrate, oxalate, fluoride, and iodoacetate. The following substances were reported to have no effect on the performance of the method at the concentrations stated: bilirubin, 5 mg/dL; hemoglobin, 95 mg/dL; ascorbic acid, 200 mg/dL; glutathione, 20 mg/dL; uric acid, 10 mg/dL; urea, 2000 mg/dL; and creatinine, 25 mg/dL.

Relative rates of reaction of other sugars with glucose dehydrogenase compared with glucose are as follows:

Substrate	Activity (%)
2-Deoxyglucose	125
Glucose	100
D-Glucosamine	31
D-Xylose	15
D-Mannose	8
Fructose	None
Galactose	None

2-Deoxyglucose does not occur in mammals. Concentrations of other reacting sugars should be negligible; however, the procedure should not be used for blood glucose determinations during oral xylose absorption tests.

OXIDATION-REDUCTION METHODS FOR GLUCOSE

Many older procedures for measuring glucose were based on its property of acting as a reducing agent in a hot alkaline solution. These are nonspecific, but some are briefly discussed because they are still used for urine glucose testing in some countries.

$$Cu^{2+} \xrightarrow{\text{alkali, heat}} Cu^{+}$$

$$Cu^{+} + OH^{-} \longrightarrow CuOH\ (\text{yellow})$$

$$2\,CuOH \xrightarrow{\text{heat}} Cu_2O\ (\text{red}) + H_2O$$

In hot alkaline solution, the aldehyde group of glucose readily reduces cupric ions to cuprous ions, which form mainly cuprous oxide (Cu_2O). The reaction is not stoichiometric, being dependent on the alkalinity, the time and temperature of heating, and the concentration of reagents. Under carefully controlled conditions, the reaction is reproducible and provides quantitative results when calibrators are analyzed in the same manner as protein-free filtrates. Reoxidation of cuprous ions by oxygen from the air is prevented by using a constricted tube to minimize the surface area or by incorporating sodium sulfate (18 g/dL) in the reagent to decrease the solubility of oxygen. Phosphomolybdic (or arsenomolybdic) acid, added in a second step, is reduced by the cuprous ion to form compounds with lower oxidation states of molybdenum. These products are blue and are suitable for photometric measurements.

1. In the *Folin-Wu* procedure, proteins are precipitated with tungstic acid, and the clear, protein-free filtrate is used in the reaction with cupric ions. The method lacks specificity, owing to the presence of nonglucose reducing substances in the filtrate, and is considered obsolete.
2. In the *Somogyi-Nelson* procedure, proteins are precipitated by the addition of $Ba(OH)_2$ and $ZnSO_4$. Protein is removed as zinc proteinate, sulfhydryl compounds as zinc salts, and the remaining zinc and barium ions as zinc hydroxide [$Zn(OH)_2$] and barium sulfate ($BaSO_4$):

$$ZnSO_4 + Ba(OH)_2 \longrightarrow Zn(OH)_2 \downarrow + BaSO_4 \downarrow$$

Uric acid and some creatinine are also precipitated and adsorbed on $BaSO_4$ so that the resultant filtrate is virtually free of nonsugar reducing substances. When the reagents are properly balanced, the filtrate has a pH of approximately 7.4. Before the advent of enzyme assays, this was the reference method for glucose, but it is now considered obsolete. Preparation of a Somogyi filtrate

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

is described earlier under Glucose Oxidase Photometric Method for Glucose.

3. In the *neocuproine* method, glucose in hot alkaline solution reduces cupric to cuprous ions. The latter form an orange complex with 2,9-dimethyl-1,10-phenanthroline (neocuproine), which is suitable for photometric measurement. The procedure is highly sensitive but relatively nonspecific. Major problems encountered are high blanks, increasing baseline values in automated systems, and interference by uric acid and ascorbic acid. Careful control of temperature and heating time is vital. Application of the method was essentially limited to continuous-flow automated systems and has been discontinued.
4. *Ferricyanide* ion (yellow) is reduced by glucose in hot alkaline solution to ferrocyanide ion (colorless).

$$\text{Glucose} + Fe^{3+}(CN)_6^{3-} \longrightarrow Fe^{2+}(CN)_6^{4-} + \text{Oxidized products of glucose}$$

The decrease in the color of ferricyanide, measured at 420 nm, is proportional to the increase in glucose concentration (inverse photometry). The reaction blank, without glucose, has the greatest absorbance, and measurements in the low or reference range are inherently less accurate, because the results are based on a small difference between large absorbance values. In addition, the maximum amount of glucose that follows Beer's law is severely restricted by the maximum color that can be measured accurately in the reagent blank. Precision is improved by automation. The alkaline ferricyanide method was in wide use when glucose determinations were performed on the Technicon Auto Analyzer. Other reducing substances interfere (e.g., 1 mg of creatinine and 1 mg of uric acid react to produce the same effect as 1 mg and 0.5 mg of glucose, respectively). Serum from a uremic patient in which both creatinine and uric acid are markedly increased exhibits a falsely elevated value for glucose. For the same reason, the alkaline ferricyanide method is unsuitable for the determination of glucose in urine. The large amounts of reducing substances liberated by hemolysis make hemolyzed specimens unacceptable.

QUALITATIVE METHOD FOR TOTAL REDUCING SUBSTANCES

Principle

Benedict's qualitative reagent contains cupric ion complexed to citrate in alkaline solution. Reducing substances convert cupric to cuprous ions, forming yellow cuprous hydroxide or red cuprous oxide (see the previous section on oxidation-reduction methods).

Dissolve 17.3 g of $CuSO_4 \cdot 5H_2O$ in 100 mL of hot water. Dissolve separately, with heating, 173 g of sodium citrate ($Na_3C_6H_5O_7 \cdot 2H_2O$) and 100 g of sodium carbonate (Na_2CO_3) in 800 mL of water. Allow to cool, then add the citrate-carbonate solution, with mixing, to the copper sulfate ($CuSO_4$) solution. Dilute to 1 L with water. This reagent is stable.

Procedure

Add 8 drops (0.4 mL) of urine to 5 mL of reagent in a test tube. Mix and place in a boiling water bath for 3 minutes. Remove and examine immediately. Report as 0 to 4+ according to the following criteria:

Appearance	Report	Approximate Glucose Concentration (g/dL)
Blue to green, no precipitate	0	0-0.1
Green with yellow precipitate	1+	0.3
Olive green	2+	1.0
Brownish-orange	3+	1.5
Brick red	4+	2.0 or more

Comments

A convenient adaptation of the foregoing procedure is marketed in tablet form (Clinitest; Bayer Corp., Elkhart, Ind.). The tablets contain anhydrous cupric sulfate, sodium hydroxide (NaOH), citric acid, and sodium bicarbonate ($NaHCO_3$). Five drops (0.25 mL) of urine are mixed with 10 drops of water in a test tube. One tablet is added, and the mixture is allowed to stand undisturbed for 15 seconds, mixed, and immediately observed for color. A chart provided by the manufacturer is used to interpret the result. Heat is generated by contact of NaOH and water. The initial reaction between citric acid and $NaHCO_3$ causes the release of carbon dioxide, which blankets the mixture and reduces contact with oxygen from the air to prevent reoxidation of cuprous ions. If large quantities (>2 g/dL) of sugar are present in the urine, the solution goes through the range of colors and back to greenish-brown. This may lead to an erroneous low reading unless the entire reaction is observed closely. Urine reacting this way should be retested with two drops of urine instead of five. As discussed earlier in the section on oxidation-reduction methods for blood glucose, false-positive interference may be caused by other reducing substances that may appear in the urine.

METHOD FOR THE DETECTION OF KETONE BODIES BY ACETEST

Principle

The Acetest tablets contain a mixture of glycine, sodium nitroprusside, disodium phosphate, and lactose. Acetoacetate or acetone (to a lesser extent) in the presence of glycine

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

forms a lavender-purple complex with nitroprusside. β-Hydroxybutyrate does not react with nitroprusside. The disodium phosphate provides an optimum pH for the reaction, and lactose enhances the color.

Specimen Collection and Storage

The serum should be free of visible hemolysis, because an excessive amount of hemoglobin may discolor the tablet or reagent strip. If there is a significant delay in performing the determination, the specimen should be kept tightly sealed at 4 °C. Urine preservatives may affect test results.

Procedure

A detailed procedure for detecting ketone bodies by Acetest is supplied by the manufacturer with each package of tablets, and readers are referred to these instructions. After adding one drop of urine, serum, or blood, the color is read at 30 seconds, 2 minutes, or 10 minutes, respectively. Acetest was designed mainly for the detection of ketone bodies in urine. If serum is used, the tablets should be crushed and a drop of serum should be added to the powder. Failure to do so results in falsely decreased values. Positive and negative controls should be performed. It has been reported that this procedure is more reliable than the Ketostix method, described later.

Comments

False-positive results may occur with urine specimens containing very large quantities of phenylketones, drugs containing sulfhydryls (e.g., angiotensin converting enzyme inhibitors), or specimens preserved with 8-hydroxyquinoline. L-Dopa metabolites may produce an atypical reaction that could be interpreted as a positive result. False-negative results have been reported with highly acidic urine specimens (e.g., after large intake of vitamin C), when reagents are exposed to air or are out of date.

A positive reaction (purple-lavender appearance) indicates the presence of ketone bodies at a concentration of 5 mg/dL (0.5 mmol/L) or greater and 10 mg/dL for urine and blood, respectively. A color chart provided with the package may be used to estimate actual concentrations of the ketone bodies. Semiquantitation is achieved by approximate values assigned to the color blocks having 20 mg/dL (2 mmol/L) for "small," 30 to 40 mg/dL for "moderate," and 80 to 100 mg/dL for "large." If required, dilutions of serum with saline can be prepared to measure concentrations of ketone bodies exceeding 80 mg/dL (note that any dilution with saline introduces some error, because the reaction is affected by proteins). Because a large reaction in an undiluted sample corresponds to approximately 80 mg/dL, a large reaction in a twofold dilution corresponds to approximately 160 mg/dL. Similar calculations can be performed with other dilutions. Ketones are not detected in blood or urine in normal carbohydrate metabolism.

Method for the Detection of Ketone Bodies by Ketostix

Ketostix is a modification of the nitroprusside test in which a reagent strip is used instead of a tablet. The Ketostix test gives a positive reaction within 15 seconds with a specimen containing at least 50 mg of acetoacetate per liter. The accompanying color chart gives readings for ketone concentrations of 50, 150, 400, 800, and 1600 mg/L. Acetone also reacts, but the sensitivity is lower.

METHOD FOR THE DETERMINATION OF β-HYDROXYBUTYRATE

Principle

β-Hydroxybutyrate in the presence of NAD^+ is converted by β-hydroxybutyrate dehydrogenase to acetoacetate, producing NADH. Diaphorase catalyzes the reduction of nitroblue tetrazolium (NBT) by NADH to produce a purple compound and its absorbance is read in a special meter that provides a digital readout.

Specimen Collection and Storage

The assay can be performed on whole blood, plasma, or serum. A sample of capillary blood obtained using a fingerstick is suitable. Hemolyzed samples should not be assayed. Whole blood can be stored at 4 °C for up to 4 hours, whereas serum or plasma may be stored at 4 °C for 48 hours or at −20 °C for a few days.

Procedure

A test card is inserted into the meter. Twenty to 30 μL of sample is carefully applied to the center of the card, and the door of the meter is closed. After 2 minutes, the result is displayed on the meter. The sample must be applied exactly to the center of the pad, and timing is critical.

Concentrations of β-hydroxybutyrate greater than 2.0 mmol/L require dilution by adding 20 μL of sample to 200 μL of GDS diluent (supplied by the manufacturer). A 20-μL aliquot of the diluted sample is read in the meter, and the result is multiplied by 11 to determine the β-hydroxybutyrate concentration. A cartridge is inserted into the meter to calibrate it to each specific lot of reagent. Low and high controls should be assayed daily.

No significant interference is reported by 2000 mg/dL of glucose, 5 mg/dL of creatinine, 16 mg/dL of uric acid, 10 mg/dL of bilirubin, 96 mg/dL of lactic acid, and 3 mg/dL of ascorbic acid. Acetoacetate has a negative interference and increasing acetoacetate concentrations progressively decrease measured β-hydroxybutyrate values. For example, an 8 mmol/L solution of acetoacetate will decrease measured β-hydroxybutyrate values by 60%. It has been recommended to either (1) test for acetoacetate before testing for β-hydroxybutyrate and dilute those specimens with increased acetoacetate concentrations or (2) routinely dilute by 1:11 all specimens before assay. Dimercaprol may falsely increase the β-hydroxybutyrate result.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

Comments

1. Considerable technical expertise is required to perform the assay, and it is not appropriate for self-monitoring. A card with a color chart that has readings of "normal," "small" (0.5 mmol/L), and "moderate" (1.5 mmol/L) is available for screening in physicians' offices or the emergency department.
2. A liquid assay that can be applied to several automated analyzers is also available.
3. While conceptually preferable to acetoacetate, clinical experience with direct measurement of β-hydroxybutyrate is limited and the data are conflicting. A 1995 short report on patients with diabetic ketoacidosis indicated that β-hydroxybutyrate correlated better than acetoacetate with changes in acid-base status. An insulin regimen using resolution of hyperketonemia (β-hydroxybutyrate <0.5 mmol/L) as the target resolved ketosis more rapidly. In contrast, other investigators concluded that frequent monitoring of serum ketone bodies added little useful information in the management of diabetic ketoacidosis. Further studies are needed to resolve these discrepancies.
4. Several methods are available as hand-held meters, which are FDA-approved for both laboratory use and for use by patients themselves.

Reference Interval

β-Hydroxybutyrate values range from 0.02 to 0.27 mmol/L (0.21 to 2.81 mg/dL) in healthy people after an overnight fast. Ketone bodies in the blood can reach 2 mmol/L with prolonged exercise. Patients with diabetic ketoacidosis usually have β-hydroxybutyrate concentrations >2 mmol/L (20 mg/dL).

METHOD FOR THE DETERMINATION OF KETONE BODIES IN URINE

Acetest and Ketostix are also suitable for detecting ketone bodies in urine. The sensitivity and specificity of the tests are the same as outlined for serum.

Procedure

Gerhardt's test is based on the reaction of ferric chloride with acetoacetate, producing a wine-red color. It is nonspecific, and other compounds such as salicylates, phenol, and antipyrine give a similar color, thus a positive reaction merely signals the possible presence of acetoacetate. To confirm its presence, urine is heated to decompose acetoacetate to acetone and to drive off the acetone. The test is then repeated. If the result is then negative, it can be assumed that the original color was caused by the acetoacetate. This test has been replaced by the Acetest and Ketostix procedures.

Rothera's test uses nitroprusside to detect urinary ketones but has been replaced by the methods described earlier.

METHOD FOR THE DETERMINATION OF LACTATE IN WHOLE BLOOD

Principle

Lactate is oxidized to pyruvate by lactate dehydrogenase in the presence of NAD^+. The NADH formed in this reaction is measured by a spectrophotometer at 340 nm and serves as a measure of the lactate concentration.

The equilibrium of the reaction normally lies far to the left. However, by using a pH of 9.0 to 9.6, an excess of NAD^+, and trapping the reaction product pyruvate with hydrazine, the equilibrium can be shifted to the right. Pyruvate can also be removed by reacting it with L-glutamate in the presence of alanine aminotransferase. Use of tris (hydroxymethyl)-aminomethane (TRIS) buffer results in more rapid completion of a side reaction between NAD^+ and hydrazine and prevents the "creeping" of blank values observed when glycine buffer is used.

Because of its high specificity and simplicity, the enzymatic method is the method of choice for measuring lactate, although other methods may also be used (e.g., gas chromatography and photometry).

The Vitros analyzer, formerly the Ektachem (Johnson & Johnson Diagnostics, Rochester, N.Y.), uses an assay in which lactic acid is oxidized to pyruvate by lactate oxidase. The H_2O_2 generated oxidizes a chromogen system, and the absorbance of the resulting dye complex, measured by a spectrophotometer at 540 nm, is directly proportional to the lactate concentration in the specimen. Each mole of lactate oxidized produces 0.5 mol of dye complex.

$$\text{L-Lactate} + O_2 \xrightarrow{\text{Lactate Oxidase}} \text{Pyruvate} + H_2O_2$$

$$2H_2O_2 + \text{4-aminoantipyrine} + \text{1,7-dihydronaphthalene} \xrightarrow{\text{Peroxidase}} \text{red dye}$$

Specimen Collection and Storage

Stringent sample preparation and handling techniques are necessary to prevent changes in lactate concentrations both during and after the blood is drawn. For metabolic studies, subjects should be fasting and at complete rest for at least 2 hours to allow lactate concentrations to reach a steady state.

Venous specimens should be obtained without the use of a tourniquet or immediately after the tourniquet has been applied. Alternatively, the tourniquet should be removed

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

after the puncture has been performed, and the blood should be allowed to circulate for several minutes before the sample is withdrawn. Arterial blood sampling, which avoids these potential pitfalls, may also be used. Patients should avoid exercise of the hand or arm immediately before and during the procedure.

Both venous and arterial blood may be collected in heparinized syringes and immediately delivered into a premeasured amount of chilled protein precipitant, such as trichloroacetic acid, metaphosphoric acid (MPA), or perchloric acid. Ideally, the first few milliliters of blood should be discarded. The clear supernatant, after centrifugation, is stable at 4 °C for as long as 8 days. Meticulous attention to sample preparation is required. Failure to completely inhibit glycolysis rapidly results in increases in blood lactate concentrations. Increases may be as great as 20% within 3 minutes and 70% within 30 minutes at 25 °C. Specimens collected as described are also suitable for determination of pyruvate.

If plasma is required as a specimen, blood should be collected in a tube containing sodium fluoride (NaF) and potassium oxalate ($K_2C_2O_4$) so that the final concentrations are 60 and 12 mmol/L, respectively. Samples are stable for up to 8 hours at 20 °C in the presence of antiglycolytic agents. In the absence of antiglycolytic agents, plasma lactate stored at 25 °C increased by twofold and threefold at 4 and 8 hours, respectively, if cells were not separated.

Sample Preparation

To an appropriate number of tared test tubes (15 × 100 mm), add 6 mL of MPA (5 g/dL). Alternatively, 4 mL of trichloroacetic acid (10 g/dL) or 4 mL of the perchloric acid (8 g/dL) may be used, but NADH is reported to be more stable with MPA. Weigh and place the tubes on ice. Perform assays in duplicate. Collect about 5 mL of arterial or venous blood in a heparinized syringe without production of air bubbles and add 2 mL of the blood to each of two tubes within 15 seconds of withdrawal.

Mix the blood with the MPA solution by three inversions of the tubes. Keep the mixture cold for an additional 10 minutes to ensure complete precipitation of proteins. Allow the tubes to warm to room temperature; determine their weights. Centrifuge for 15 minutes at 3000 × *g* or for at least 30 minutes at 1500 × *g*. The supernatant must be clear, and if necessary, a second centrifugation is performed. The supernatant is stable for 8 days at 4 °C or 6 weeks at −20 °C.

Determine the dilution factor (D) as follows:

$$D = \frac{W_b - W_t}{W_b - W_m}$$

where W_t is the weight of the empty tube, W_m is the weight of the tube plus MPA solution, and W_b is the weight of the tube plus the MPA and blood. If the method is followed as described, the dilution factor should be approximately four.

Reagents

1. MPA, 5 g/dL. Dissolve 5 g of MPA in water and dilute to 100 mL. Prepare fresh daily (see Comments, later).
2. MPA, 3 g/dL. Dissolve 3 g of MPA in water and dilute to 100 mL. Prepare fresh daily.
3. TRIS-hydrazine buffer mixture, pH 9.6 (TRIS, 79 mmol/L; hydrazine, 400 mmol/L). To about 700 mL of NaOH, 1 mol/L, add 9.57 g of TRIS, 52 g of hydrazine sulfate, and 1.85 g of EDTA · Na_2 (to chelate metal ions and prevent inhibition of lactate dehydrogenase). Adjust the pH to 9.6 with NaOH, 1 mol/L, and dilute the solution to 1000 mL with distilled water. This buffer is stable for 8 days at 4 °C.
4. NAD^+ solution, 27 mmol/L. Dissolve purified NAD (grade 1, Boehringer) in distilled water to obtain a 20-mg/mL solution. This solution is stable for about 48 hours at 4 °C.
5. Lactic dehydrogenase solution. Dilute the stock solution (Sigma, type III, crystalline bovine heart lactate dehydrogenase, 10 mg protein/mL) with saline to a protein concentration of 3 mg/mL (0.3 mL of stock diluted to 1.0 mL). Keep refrigerated and use within 48 hours.
6. Lactate calibrator, 1 mmol/L (9 mg/dL). Dissolve 9.60 mg lithium L-lactate (Calbiochem, A grade, San Diego) in water in a 100-mL volumetric flask. Add 25 µL concentrated sulfuric acid (H_2SO_4) and bring to volume with water. Stability is indefinite at 4 °C. Lactate stock calibrators are also commercially available.

Procedure

1. To each of three cuvets labeled test, calibrator, and blank, respectively, add 2.0 mL of TRIS-hydrazine buffer.
2. Add 0.1 mL of supernatant solution to the test cuvet, 0.1 mL of lactate calibrator to the calibrator cuvet, and 0.1 mL of MPA (3 g/dL) to the blank cuvet.
3. Mix the solutions and add 30 µL of lactate dehydrogenase solution and 0.2 mL of NAD^+ solution to each cuvet.
4. Mix the contents again; after 15 minutes at room temperature, measure the absorbance at 340 nm against the blank. A separate reagent blank and working calibrator should be determined with each run.

Results obtained with the lactate method are linear up to concentrations of approximately 5.6 mmol/L (50 mg/dL).

Calculation

$$\text{Lactate (mmol/L)} = \frac{A_t}{A_c} \times 1 \times D$$

where t and c stand for the test and calibrator, respectively, and D is the dilution factor.

Alternatively, using the molar absorptivity of NADH,

$$\text{Lactate (mmol/L)} = A_t \times \frac{2.33}{6.22} \times \frac{D}{0.1}$$

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

where

A_t = absorbance of the test
2.33 = total volume of the test in mL
6.22 = millimolar absorptivity for NADH
0.1 = volume of supernatant in mL

To convert millimoles per liter to milligrams per deciliter, multiply by 9.

Comments

MPA is generally composed of a variable mixture of MPA and sodium metaphosphate ($NaPO_3$). In aqueous solution, MPA forms several polymers $(HPO_3)_x$, which hydrolyze to the ortho acid as follows:

$$HPO_3 + H_2O \longrightarrow H_3PO_4$$

Because orthophosphoric acid (H_3PO_4) does not precipitate proteins, MPA solutions retain their protein-precipitating activity for only about 1 week at 4 °C.

MPA is preferred by some as the protein-precipitating agent, because perchloric acid does not precipitate mucoproteins and interferes with the enzymatic method for pyruvate (if this analyte is determined on the same filtrate as lactate). Also the enzymatic lactate dehydrogenase reaction is reported to proceed much more slowly in the presence of perchloric acid.

METHOD FOR THE DETERMINATION OF FRUCTOSAMINE

Principle

Under alkaline conditions, products with Amadori rearrangements (such as fructosamine) have reducing activity that can be differentiated from other reducing substances. In the presence of carbonate buffer, fructosamine rearranges to the eneaminol form, which reduces NBT to a formazan. The absorbance at 530 nm is measured at two time points and the absorbance change is proportional to the fructosamine concentration. The 10-minute incubation is necessary to allow fast-reacting, interfering-reducing substances to react. It is unnecessary to remove endogenous glucose from patients' samples, because a pH greater than 11 is required for glucose to reduce NBT. The assay is easily automated and has excellent between-batch analytical precision. Hemoglobin (>100 mg/dL) and bilirubin (>4 mg/dL) interfere; therefore moderate to grossly hemolyzed and icteric samples should not be used. Ascorbic acid concentrations >5 mg/dL may cause negative interference. Kits are commercially available (Roche Diagnostics, Indianapolis, Ind.). An assay that measures fructosamine by oxidizing the ketoamine bond using ketoamine oxidase, with the release of H_2O_2 that is quantified by a colorimetric reaction, is available (Randox, Oceanside, Calif.). An FDA-approved device using a handheld meter for home use by adults (excluding pregnant women and children [InCharge, LXN Corp., San Diego]) has been discontinued.

Specimen Collection and Storage

Draw nonfasting venous blood in a plain tube; allow it to clot and separate within 24 hours. Plasma or serum is suitable. Samples may be stored for 3 days at 25 °C or 7 to 14 days at 4 °C. Original reports indicated that samples could be stored for several months at −20 °C, but large changes have been observed in frozen samples. Prolonged storage at ultralow temperatures (−196 °C) prevents in vitro glycation of serum proteins.

Reagents

1. Working reagent. One liter of solution contains 200 mmol of Na_2CO_3, 2.88 µmol of NBT, 22 g of nonionic detergent (e.g., Tween 20, Tensides, or Triton X-100), and 15 U of uricase, adjusted to pH 10.3. It remains stable for as long as 14 days at 4 °C in the dark.
2. Calibrator, glycated polylysine. Prepare 1 mmol glycated polylysine in 1 L of 10 mmol/L HCl. Perform serial dilutions to obtain working concentrations of 0.25, 0.5, 0.75, and 1 mmol/L. Store in the dark at 4 °C for 4 weeks or at 22 °C for 1 week. Secondary calibrators of normal human serum containing glycated protein are commercially available (Roche Diagnostic Systems).

Procedure

1. Pipette 50 µL of working calibrator, plasma, or serum into respective test tubes.
2. Add 1 mL of working reagent to each tube and mix.
3. Incubate all tubes at 37 °C.
4. Measure absorbance at 530 nm at both 10 and 15 minutes.
5. The change in absorbance between 10 and 15 minutes is proportional to the amount of fructosamine in the sample.

Comments

1. The procedure is inexpensive and rapid and has been adapted to a wide variety of automated chemistry analyzers. An automated method that measures the increase in absorbance in the 9- to 10-minute interval after the start of the reaction has been described. The assay, which measures absorbance bichromatically at 546 and 700 nm, has intraassay and interassay CVs <2% and is linear up to 1000 µmol/L.
2. Assays should be calibrated against glycated polylysine.
3. The precision of the assay is good, and a study of 33 routine laboratories using the same calibrator with a manual method and five different analyzers demonstrated a CV of 5.4%.
4. Changes in red blood cell lifespan and hemoglobin variants do not alter fructosamine values, but they are affected by total plasma protein concentrations. Patients with serum albumin concentrations <30 g/L or urinary protein concentration >1 g/L have increased albumin turnover, rendering interpretation of fructosamine values difficult.

Schleicher ED, Vogt BW. Standardization of serum fructosamine assays. Clin Chem 1990;36:136-9.

REFERENCE INTERVALS

Values in a nondiabetic population range from 205 to 285 μmol/L. The reference interval corrected for albumin is 191 to 265 μmol/L.

ELISA METHOD FOR MEASURING URINARY ALBUMIN

Both competitive and "sandwich" ELISAs are available. Although the competitive ELISA is faster because it uses only one incubation with antibody, it is reported to be less sensitive and exhibits large imprecision. ELISA can be performed on a microplate reader, allowing semiautomation. In the sandwich assay, the primary antibody (antialbumin antiserum) is fixed on the plastic plate, which is then washed. Samples, controls, and calibrators are added and the complexes detected and quantified by a second antibody conjugated to an enzyme label.

REAGENTS

1. Buffer A. Prepare 20 mmol of diethylmalonic acid, 150 mmol of NaCl, 0.1 mmol of EDTA, and 1 mL of Tween 20 (surfactant) in 1 L of distilled water and adjust to pH 7.4 with 1 mol/L potassium hydroxide. Add 5 g of gelatin, dissolving by gentle stirring at 37 °C. This may be stored at room temperature for 7 days or at 4 °C for 1 month. The slightly turbid refrigerated solution should be clarified by warming at 37 °C or 25 °C.
2. Stock albumin calibrator, 1 g/L. Dissolve 10 mg of human serum albumin (HSA) in 10 mL of 0.1 mol/L $NaHCO_3$. Store in 0.1-mL aliquots at −20 °C for 1 year. The concentration can be checked by using an absorptivity of 0.54 at 280 nm for 1 g/L albumin solution.
3. Coating solution, 0.2 mg/L albumin. Dilute the stock albumin calibrator by adding 0.1 mL to 499.9 mL of 0.1 mol/L $NaHCO_3$.
4. Stock conjugate solution, rabbit antihuman albumin-peroxidase conjugate (Organon Teknika-Cappel, Malvern, Pa.). Stock conjugate is 11 mg of IgG and 4 mg of peroxidase per milliliter. Dilute 0.1 mL with 9.9 mL of buffer A and store in 0.1-mL aliquots at −20 °C.
5. Conjugate, working solution 1:20,000. Add 0.1 mL of stock conjugate to 19.9 mL of buffer A.
6. Substrate, 0.5 mmol/L of 3,3′,5,5′-tetramethylbenzidine dihydrochloride (TMB). Dissolve 10 mg of TMB in 4 mL of distilled water and add to 56 mL of potassium acetate buffer (50 mmol/L, pH 4.5). Immediately before assay, add 6 μL of concentrated H_2O_2 (500 g/L). This should be prepared fresh daily.

PROCEDURE

1. Fill the wells of Immulon 2 microplates (rows B-H) with 0.10 mL of coating solution (0.2 mg/L HSA). Incubate the covered plates for 3 hours at 37 °C, then overnight (12 hours) at 4 °C. Plates may then be stored at 4 °C for up to 4 weeks in sealed plastic bags or washed three times with buffer A and stored for 4 weeks or longer before use.
2. Perform assays in duplicate, using samples of settled urine diluted in polypropylene tubes with buffer A either 100-fold (normal), 200-fold (diabetic), or 1000-fold (proteinuric).
3. Prepare HSA calibrators by diluting stock HSA 1000-fold with buffer A and further diluting with buffer A to give calibrators ranging in concentration from 0 to 1.00 mg/L.
4. Wash the coated plates four times with buffer A.
5. Add 50 μL of sample or calibrator to the wells of the coated plate.
6. Add 50 μL of conjugate (1:20,000) to all the wells and incubate the covered microplate for 1 hour at 37 °C.
7. Wash the microplate four times with buffer A and add 0.20 mL of TMB substrate to each well. Immediately place the microplate on a microplate mixer, incubating until the maximal absorbance reaches 1.5 to 2.0 (about 15 minutes).
8. Remove the plate from the mixer and measure its absorbance at 650 nm. Albumin concentrations in the samples are determined by comparison with the calibration curve.

COMMENTS

1. The assay uses TMB, which is noncarcinogenic, as the peroxidase substrate.
2. The assay is linear from 30 to 300 μg/L and can detect as little as 10 μg/L.
3. Competitive ELISA assays that do not require overnight incubation have been described.

AN IMMUNOTRUBIDIMETRIC METHOD FOR MEASURING URINARY ALBUMIN

PRINCIPLE

Albumin in the urine sample forms an insoluble complex with antibodies to human albumin. PEG accelerates complex formation. The turbidity caused by the complexes is measured by a spectrophotometer at 340 nm and is a measure of albumin concentration. The background absorbance of the initial urine sample is subtracted automatically. This

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

method is simple and less expensive than RIA, and rapid analysis of large numbers of samples is possible. The assays may be performed as either kinetic or equilibrium reactions. An equilibrium method is described here. Kits are commercially available for use on automated analyzers (Roche Diagnostics).

Reagents

1. Phosphate-buffered saline, 50 mmol/L, pH 7.3. Dissolve 8.8 g NaCl (150 mmol/L), 40 g of PEG 6000, 4.34 g of anhydrous Na_2HPO_4, 2.64 g of KH_2PO_4, 0.2 mL Tween 20 surfactant, and 1 g of NaN_3 in 900 mL of distilled water. Adjust the pH to 7.3 and dilute to 1 L.
2. Antiserum. Rabbit anti-human albumin antibody, 0.8 g/L or greater.
3. NaCl, 150 mmol/L. Dissolve 8.8 g of NaCl in about 800 mL of distilled water and dilute to 1 L.
4. Albumin calibrator, 1 g/L. Dissolve 1 g of human albumin (Miles Laboratories) in 1 L of 150 mmol/L NaCl.

Procedure

1. Dilute the urine sample by pipetting 20 µL of urine into a test tube and adding 180 µL of 150 mmol/L NaCl.
2. Pipette 50 µL of undiluted calibrator and diluted urine into each of two cuvets.
3. Add 850 µL of assay buffer to each tube and mix.
4. Incubate for 10 minutes at 37 °C.
5. Measure the absorbance at 340 nm.
6. Add 100 µL of antiserum to human albumin to each tube and mix.
7. Allow to incubate for 2 minutes at 37 °C and read the absorbance at 340 nm. Subtract the initial absorbances.
8. Plot the absorbance of each calibrator against its albumin concentration. The albumin concentration of the sample is read off the calibration curve.

Comments

1. Urine albumin concentrations can be measured from 3 to 400 mg/L for undiluted urine. This range can be extended to 4 g/L by diluting urine tenfold.
2. This method is easy and rapid, and as many as 200 determinations can be performed in 20 minutes with automation.
3. High antigen concentrations may cause a "hook" effect, resulting in falsely low concentrations. This can be prevented by screening urine samples with a dipstick, but may not be necessary if the analyzer automatically tests for antigen excess.
4. These methods lack sensitivity, but linking antibodies to latex particles is reported to enhance the sensitivity.
5. A urinary tract infection or contamination with seminal or menstrual fluid may produce false-positive results.
6. High physiological Ca^{2+} concentrations in the urine falsely elevate albumin levels. The interference is abolished by the addition of EDTA, which has been incorporated into a commercial assay (Roche Diagnostics).

Reference

Teppo AM. Immunoturbidimetry of albumin and immunoglobulin G in urine. Clin Chem 1982;28: 1359-61.

Reference Intervals

	Urinary Albumin Excretion		
	µg/min	mg/24 hr	Corrected (mg/g urine creatinine)
Normal	<20	<30	<30
Increased UAE	20-200	30-300	30-300
Clinical albuminuria*	>200	>300	>300

*Also termed "overt nephropathy."

The ADA recommends initial UAE measurement in type 1 diabetes patients who have had diabetes ≥5 years and in all type 2 diabetic patients. Because of the difficulty in dating the onset of type 2 diabetes, screening should commence at diagnosis. Analysis should be performed annually in all patients who have a negative screen. Screening may be performed with a semi-quantitative assay. If the screen is positive, UAE should be evaluated by a quantitative assay. Diagnosis requires the demonstration of increased UAE in at least two of three tests measured within a 6-month period.

If the confirmatory test is positive, treatment with an angiotensin-converting enzyme (ACE) inhibitor or angiotensin-receptor blocker should be initiated. ACE inhibitors delay the progression to overt nephropathy and the National Kidney Foundation recommends their use in both normotensive and hypertensive type 1 and 2 diabetic patients. The role of monitoring UAE in patients on ACE inhibitor therapy is less clear, although many experts recommend continued surveillance. Untreated, the UAE would increase 10% to 30% per year, whereas the albumin:creatinine ratio in patients on ACE inhibitors should stabilize or decrease by up to 50%.

METHOD FOR THE IDENTIFICATION OF URINARY SUGARS BY PAPER CHROMATOGRAPHY

Principle

Sugars can be separated by ascending or descending chromatography on paper and located after color development with dinitrosalicylic acid. The variable rates of migration depend on the solubility of the sugars in the particular solvent system. Presumptive identification is made by comparison of the migration (R_f) value of the unknown with those of reference compounds. The following procedure may

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

be performed conveniently in a 6 × 18-inch Pyrex jar with a tightly fitting cover.

Reagents

1. Solvent. Perform the following procedure under a hood. Mix 60 mL of *n*-butanol, 40 mL of pyridine, and 30 mL of distilled water. The mixture is completely miscible. Pour it into the bottom of the jar, cover, and allow to equilibrate at least 30 minutes before use.
2. Spray reagent. Dissolve 0.5 g of 3,5-dinitrosalicylic acid in 100 mL of NaOH solution (4 g/dL).
3. Reference sugar solutions. Prepare solutions of glucose, fructose, galactose, maltose, lactose, and xylose to contain 1.75 g of each in 100 mL of benzoic acid solution (2 g/L). These solutions are stable for months.

Procedure

1. Estimate the concentration of sugar in the urine by means of one of the qualitative copper reduction tests. Dilute the specimen, if necessary, to a sugar concentration of approximately 1 g/dL. If the concentration is only 0.5 g/dL, use twice as much sample in the test.
2. Draw a pencil line 2.5 cm from and parallel to the 25-cm side of a 25 × 35 cm section of Whatman No. 1 filter paper. Place pencil marks 2.5 cm apart on the line to designate starting positions for each reference sample and for the urine specimen.
3. Apply 10 µL of each solution to its respective point. Half of this amount should be applied and permitted to dry before adding the remainder to keep the diameter of the spots as small as possible. Allow all samples to dry completely.
4. Insert the sheet into a 35-cm-high cylinder so that the line of application is at the bottom. Staple the edges together. Insert the paper into the chromatography jar, tape on the cover, and allow to stand undisturbed for about 16 hours (overnight) at room temperature.
5. Remove the sheet and mark with a pencil along the solvent front. Allow to air dry under a hood.
6. Spray the sheet with dinitrosalicylic acid reagent from an atomizer and allow to air dry.
7. Heat the paper at 100 °C for 10 minutes in a drying oven. The reducing sugars appear as brown spots against a yellow background.
8. Measure the distance from the starting line to the edge of the solvent front. Calculate the R_f:

R_f = Distance traveled by solute spot/Distance traveled by solvent front.

The R_f values vary slightly from run to run, and for this reason known reference samples should be included each time. Average values are as follows:

Sugar	R_f
Lactose	0.22
Maltose	0.28
Galactose	0.36
Glucose	0.41
Fructose	0.46
Xylose	0.52

The unknown sugar in the urine is presumed to be the same as a known reference compound when both migrate the same distance under the test conditions. For confirmation, the urine specimen may be mixed with an equal volume of the known reference and rechromatographed. Only one sugar spot appears on the paper if the two sugars are identical. Dinitrosalicylic acid is a highly specific reagent for reducing sugars.

Other reagents to detect reducing substances in urine have also been used. Phloroglucinol reagent, for example, produces a faint brown reaction with galactose, orange-brown with fructose, and greenish-blue with pentoses. No color is produced with lactose, maltose, or glucose. The reagent is prepared by dissolving 0.2 g of phloroglucinol in 80 mL of 90% ethanol (900 mL ethanol/L) and diluting to 100 mL with trichloroacetic acid solution (250 g/L).

APPENDIX 26

Lipids, Lipoproteins, Apolipoproteins, and Other Cardiovascular Risk Factors

Nader Rifai, Ph.D.,
and G. Russell Warnick, M.S., M.B.A.

The following are several methods for separating lipoprotein fraction for subsequent analysis.

HIGH-DENSITY LIPOPROTEIN CHOLESTEROL[323]*

DEXTRAN SULFATE-$MgCl_2$ METHOD

This is the Selected Method for HDL cholesterol and is similar to the Designated Comparison Method currently used as the target for HDL cholesterol analysis in the CRMLN laboratories (Cholesterol Reference Method Laboratory Network).

Reagents

1. Stock solutions. Dextran sulfate (20 mg/mL; Dextralip 50, MW 50,000 Da, Sigma Diagnostics, St. Louis Mo.). Dissolve 2.0 g dextran sulfate in deionized H_2O. Adjust to pH 7.0 with 0.05 mol/L HCl. Transfer the solution quantitatively to a volumetric flask and bring to 100 mL. Store at 4 °C.
2. $MgCl_2$, 1.0 mol/L. Use reagent grade $MgCl_2 \cdot 6H_2O$. Dissolve 20.3 g in deionized H_2O and adjust to pH 7.0 with 0.05 mol/L NaOH. Transfer the solution quantitatively to a volumetric flask and adjust to 100 mL. Store at 4 °C.
3. Working solution. Mix equal volumes of the dextran sulfate and $MgCl_2$ stock solutions.

*References are found in Ch. 26 of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*, edition 4.

Procedure

1. Allow working reagent and samples to reach room temperature.
2. Transfer 1.0 mL serum or plasma to a test tube.
3. Add 100 µL of working reagent solution.
4. Mix well using a vortex mixer.
5. Allow mixture to stand at room temperature for 10 minutes.
6. Centrifuge for 45,000 *g*/min. Centrifugation can be performed at 1500 × *g* for 30 minutes in a refrigerated centrifuge or alternatively at 15,000 × *g* for 3 minutes.
7. Remove an aliquot of the clear supernatant for measurement of HDL cholesterol.
8. Multiply the measured value by 1.1 to correct for dilution by the reagent.

HEPARIN-$MnCl_2$ METHOD

This procedure is similar to that used in the CDC Reference method for HDL cholesterol.[158]

Reagents

1. $MnCl_2$, 1.0 mol/L. Dissolve 98.96 g reagent grade $MnCl_2 \cdot 4H_2O$ in H_2O. Transfer to a 500-mL volumetric flask and bring to 500 mL. Store at 4 °C.
2. $MnCl_2$, 2.0 mol/L. Same as above, but use 197.91 g $MnCl_2 \cdot 4H_2O$.
3. Heparin, 5000 USP units/mL. Using a volumetric pipette, add 1.0 mL heparin (40,000 U/mL) to 7.0 mL 0.15 mol/L NaCl. Store in a sealed container at 4 °C.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

Procedure

1. Allow reagents and specimens to reach room temperature. Mix specimens by inversion.
2. Transfer 1.0 mL serum or plasma to a clear centrifuge tube.
3. For serum: Add 40 µL heparin solution and 50 µL 1.0 mol/L $MnCl_2$ solution. For plasma add 40 µL heparin solution and 50 µL 2.0 mol/L $MnCl_2$ solution.
4. Mix well on a vortex type of mixer.
5. Allow the mixture to stand at room temperature for 15 minutes or in an ice bath for 30 minutes.
6. Centrifuge the mixture for 45,000 *g*/min (equivalent to 1500 × *g* for 30 minutes).
7. Remove an aliquot of the clear supernatant for measurement of HDL cholesterol using a cholesterol method that is not sensitive to interference by Mn^{2+}.
8. Multiply the observed HDL cholesterol concentration by 1.09 to correct for dilution by the reagents.

Ultracentrifugation to Remove Triglyceride-Rich Lipoprotein

The following procedure is used to remove VLDL, β-VLDL, and chylomicrons from plasma. The method uses 5.0 mL of sample but can be scaled down to 3.0 mL, if necessary.

Procedure

1. Place 5.0-mL EDTA plasma samples into heat-sealable 13 × 64 mm ultracentrifuge tubes (available from Beckman Coulter Instruments, Palo Alto, Calif.).
2. Carefully overlay each sample with a sufficient volume of 0.15 mol/L NaCl to bring the level to the neck of the ultracentrifuge tube. Be sure to equalize the weight of all tubes so that the ultracentrifuge rotor is balanced during operation.
3. Seal the tubes and place them into a precooled type 50.3 rotor (Beckman Coulter Instruments).
4. Centrifuge the samples at 10 °C for at least 18 hours at 105,000 × *g*. As a matter of convenience, the centrifugation time can be extended an hour or two if necessary.
5. At the end of the centrifugation period, allow the rotor to come to rest without braking to avoid disturbing the layers.
6. Carefully remove the tubes from the rotor and place them into a tube rack in an ice bath.
7. Observe the tubes. A floating, white layer of triglyceride-rich lipoproteins should be observed at the top of the tube. There should be a water-white clear zone that extends 1 cm or more below the floating layer. A colored zone containing lipoproteins of density >1.006 g/mL should appear near the bottom of the tube, layered above a zone containing the remaining, denser plasma proteins.
8. Place the tube into a tube slicer and adjust its position such that the tube slicer blade strikes the tube about 11 mm below the shoulder of the tube and in the water-white clear zone. This distance may have to be increased somewhat for a sample with a high triglyceride concentration that may have a wide floating layer.
9. Strike the blade handle of the tube slicer with a single, sharp blow to cut the tube cleanly and rapidly. This separates the supernatant and infranatant fractions from each other.
10. Without withdrawing the blade, carefully remove the top portion of the tube while aspirating the supernate. This can be done with a small syringe equipped with a blunt-tipped needle. Transfer the supernate to a 5.0-mL volumetric flask. Wash the blade and sample compartment portion of the tube slicer with a small amount of 0.15 mol/L NaCl and add the washing to the supernate. Then adjust the volume of the supernate to 5.0 mL.
11. Withdraw the blade of the tube slicer carefully. With the aid of a clean 5-mL syringe equipped with a blunt-tipped needle, remove some of the infranate to lower the fluid level below the rim of the bottom portion of the ultracentrifuge tube and transfer to a 5.0-mL volumetric flask. At this point, the bottom portion of the tube can be removed from the tube slicer. Recover the rest of the infranate and add to the volumetric flask. Wash the tube with a little 0.15 mol/L NaCl and add the washings to the flask. Bring the volume to 5.0 mL.
12. Mix each of the fractions by inversion. Allow the fractions to sit undisturbed in an ice bath. Allow enough time for the packed proteins in the infranate to redissolve completely.
13. Mix the fractions again by inversion, then transfer to sealable containers. Screw-capped scintillation vials equipped with polyethylene- or Teflon-lined caps can be used for this purpose. Do not use foil-lined caps. Store the fractions at 4 °C for further analysis.

The cholesterol concentrations of the two fractions are measured with the usual methods. The recovery of cholesterol in the two fractions should average about 95% or more. Ultracentrifugation should be repeated if the recovery is less than 90%. If a 3.0-mL sample is used and the fractions are reconstituted to 5.0 mL, the measured cholesterol value should be multiplied by 1.67.

APPENDIX 27

Electrolytes and Blood Gases

Mitchell G. Scott, Ph.D., Vicky A. LeGrys, D.A., M.T.(A.S.C.P.), C.L.S.(N.C.A.), and James Stacey Klutts, M.D., Ph.D.

P_{50} PROCEDURE

The simplest method for determining P_{50} consists of measuring PO_2 and SO_2 on an anaerobically collected venous whole-blood sample.[56*] pH and PCO_2 should be measured along with the other parameters. The following equation is used for calculating P_{50}:

$$\log P_{50} = \log PO_2 - \operatorname{logit} SO_2/2.7$$

where logit $SO_2 = \log[SO_2/(1 - SO_2)]$ and 2.7 is the Hill slope. This equation is a useful approximation provided the measured SO_2 is in the interval 0.4 to 0.8 (40% to 80% when expressed as a percent), thus requiring the use of venous blood in most instances. Here, it is important that SO_2 and not FO_2Hb be used in the calculations because P_{50} refers to 50% SO_2 (i.e., only hemoglobin capable of binding and releasing O_2). The measured value may then be corrected to a standard pH (7.40) and PCO_2 (40 mm Hg), providing the "standard" P_{50} using the coefficients of change in Figure 27-3 of the textbook.

The standard P_{50} thus defined may be interpreted as an indirect measure of the 2,3-DPG concentration of the erythrocytes, because an increase or decrease in 2,3-DPG concentration is the most common cause of an increase or decrease in P_{50}. However, other causes should be kept in mind, such as increases in COHb, MetHb, or HbF (decreased standard P_{50}) or congenital hemoglobin variants (causing both increased and decreased standard P_{50}). A nomogram for obtaining P_{50} from measurements of PO_2, SO_2, pH, and [2,3-DPG] has been devised.[91] In the presence of COHb, MetHb, or HbF, a computer program is needed.[95]

*References are found in Ch. 27 of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnosis*, edition 4.

Reference Intervals[101]

For adults, the 95% limits for P_{50}, measured at 37 °C and corrected to pH(P) of 7.4, are 25 to 29 mm Hg. For newborn infants, the interval is 18 to 24 mm Hg because of the presence of fetal Hb (HbF).

Clinical Significance

Increased values for P_{50} indicate displacement of the O_2 dissociation curve to the right (i.e., a decreased affinity of the hemoglobin for O_2). The chief causes are hyperthermia, acidemia, hypercapnia, high concentrations of 2,3-DPG, or presence of a hemoglobin variant with decreased O_2 affinity. 2,3-DPG concentrations tend to be increased in chronic alkalemia, anemia, and chronic hypoxemia. An example of hemoglobin with decreased O_2 affinity is hemoglobin Kansas.[7]

The physiological effects of decreased affinity of hemoglobin are small. In general, the affinity is still sufficient to allow the hemoglobin to bind adequate amounts of O_2 in the lungs. Low affinity facilitates dissociation of O_2Hb at the peripheral tissue cell. Indeed, in anemia, low affinity (as a result of increases in 2,3-DPG) is a desirable compensatory mechanism. Patients with hemoglobin Kansas have a P_{50} of approximately 80 mm Hg and a low *c*tHb, but are otherwise unaffected.[7]

Low values for P_{50} signify displacement of the O_2 dissociation curve to the left (i.e., increased affinity of hemoglobin). The main causes are hypothermia, acute alkalemia,

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

hypocapnia, low concentration of 2,3-DPG, increased COHb and MetHb, or a hemoglobin variant. Decreases of 2,3-DPG are commonly observed in acidemic states that have persisted for more than a few hours; the initial increase in P_{50} caused by the acidemia is gradually compensated for by a decrease in 2,3-DPG so that P_{50} then falls to lower than normal values.

The physiological consequence of increased affinity of hemoglobin for O_2 is less efficient dissociation of O_2Hb at the peripheral tissues and lower tissue PO_2. Patients with hemoglobin Yakima have a P_{50} of approximately 12 mm Hg, but they are compensated by an increase in *c*tHb. These patients are relatively unaffected, except for reduced stamina during strenuous exercise.

APPENDIX 29

Catecholamines and Serotonin

Thomas G. Rosano, Ph.D., Graeme Eisenhofer, Ph.D., Ronald J. Whitley, Ph.D., Ravinder Jit Singh, Ph.D., Mark M. Kushnir, M.S., Elizabeth L. Frank, Ph.D., D.A.B.C.C., F.A.C.B., Mark J. Magera, B.S., M.A., Dietrich Matern, M.D., and Piero Rinaldo, M.D., Ph.D.

SELECTED METHODS FOR ANALYSIS OF CATECHOLAMINES, SEROTONIN, AND THEIR METABOLITES

Numerous methods have been proposed for the determination of catecholamines, serotonin, and their metabolites in biological fluids. In this section, the following methods are presented:

Method 29-1. Determination of Plasma Free Catecholamines by HPLC/EC

Method 29-2. Determination of Plasma Free Metanephrines by Liquid Chromatography With Electrochemical Detection

Method 29-3. Determination of Plasma Free Metanephrine and Normetanephrine by LC-MS/MS

Method 29-4. Determination of Urinary Free Catecholamines by HPLC/EC

Method 29-5. Determination of Urinary Free Catecholamines by LC-MS/MS

Method 29-6. Determination of Urinary Metanephrine and Normetanephrine by HPLC/EC

Method 29-7. Determination of Urinary Metanephrine and Normetanephrine by LC-MS/MS

Method 29-8. Determination of Urinary Vanillylmandelic Acid by HPLC/EC

Method 29-9. Determination of Urinary Vanillylmandelic Acid by LC-MS/MS

Method 29-10. Determination of Urinary Homovanillic Acid (3-Methoxy-4-Hydroxyphenylacetic Acid) by HPLC/EC

Method 29-11. Determination of Urinary Homovanillic Acid by LC-MS/MS

Method 29-12. Determination of Urinary 5-Hydroxyindoleacetic Acid by Quantitative HPLC

Method 29-13. Determination of Urinary 5-Hydroxyindole-3-Acetic Acid by LC-MS/MS

METHOD 29-1 Determination of Plasma Free Catecholamines by HPLC/EC

Submitted by Ronald J. Whitley, Ph.D.
Department of Pathology and Laboratory Medicine, College of Medicine, University of Kentucky Medical Center, Lexington, Kentucky

Principle

Free catecholamines are first rapidly adsorbed from plasma onto aluminum oxide at pH 8.6. After washing with water, the catecholamines are then desorbed with a small volume of perchloric acid. Subsequent separation of the individual catecholamines is achieved by HPLC under optimum isocratic conditions. A silica-based cation exchange column is used as the stationary phase, and an organic/aqueous buffer mixture, pH 6.5, is used as the mobile phase. A thin-layer glassy carbon working electrode in conjunction with an Ag/AgCl reference electrode is used as the amperometric detection system. Each catecholamine passing through the detector cell undergoes a rapid two-electron oxidation at a fixed potential to form an o-quinone:

The current resulting from this reaction is converted to a voltage signal and monitored as a function of time. At a constant temperature and flow rate, this oxidation current is directly proportional to the concentration of the analyte. Catecholamine reference materials are used to calibrate the system on the basis of peak heights and retention times. To calculate sample concentrations, peak height ratios relative to the internal standard (dihydroxybenzylamine) for unknowns are compared with those of the calibrations.

Specimen Collection and Storage

Different methods of blood collection have been reported; variations among them include the choice of anticoagulant, the addition of antioxidants, and various sample processing techniques. Standardization of posture is essential because plasma catecholamine levels increase twofold to threefold when a supine subject assumes an upright position. Most procedures recommend that morning specimens be drawn from subjects who have been resting quietly for 30 minutes in a recumbent position after insertion of a venous catheter. In addition, subjects should refrain from eating, using tobacco, or drinking coffee or tea for at least 4 hours before venipuncture. If at all possible, specimens should be obtained when patients are drug free. Most antihypertensive drugs (other than clonidine) and many other drugs can produce false-positive results. Use of these drugs should be discontinued 3 to 7 days before obtaining the sample. If hypertension must be treated before measuring catecholamines, then clonidine is preferred because this drug does not produce a false-positive result.

Catecholamines in general are unstable compounds and can be readily oxidized. To prevent this oxidation, many procedures recommend that blood samples be transported to the laboratory on ice, centrifuged at 4 °C within 30 minutes of collection, and the plasma removed and frozen at −70 °C until analysis. Two anticoagulants are commonly used, heparin and ethylenediaminetetraacetic acid (EDTA), with or without the addition of antioxidants such as glutathione or metabisulfite. Advocates of a more liberal and less constrained method of collecting and processing blood catecholamines recommend the use of heparin without added preservatives. Catecholamine values from heparinized blood appear to be quite stable after separation (24 hours at 20 °C, 48 hours at 4 °C, 1 month at −20 °C). At −70 °C, catecholamines in heparin or EDTA plasma are stable for at least 8 months without the addition of preservatives.

Reagents

1. Perchloric acid ($HClO_4$), 72%, analytical grade.
2. Perchloric acid, 0.1 mol/L. Mix 8.6 mL 72% $HClO_4$ with distilled water to a final volume of 1 L.
3. Potassium hydroxide (KOH), 4 mol/L. Dissolve 112.2 g of KOH in 400 mL distilled water and dilute to 0.5 L. Store tightly capped. Stable for 1 year at room temperature.
4. Phosphoric acid (H_3PO_4), 85%, analytical grade.
5. Phosphoric acid, 2 mol/L. Mix 135 mL 85% H_3PO_4 with distilled water to a final volume of 1 L.
6. Acetonitrile, HPLC grade.
7. Catecholamine-free plasma. Obtain one unit of frozen plasma from a blood bank (approximately 300 mL). Remove residual catecholamines as follows:
   a. Thaw and transfer the plasma to 50-mL centrifuge tubes.
   b. Incubate all tubes in a water bath at 56 °C for 60 minutes.
   c. Centrifuge all tubes for 10 minutes at 3000 rpm.
   d. Remove an aliquot of the supernatant and analyze for catecholamines. If catecholamines are present, discard the entire unit of plasma. Otherwise, pipette 4.0-mL aliquots of the catecholamine-free plasma into storage vials.
   e. Freeze all aliquots. Store at −70 °C. Stable for 1 month.
8. Catecholamine stock calibrator. Weigh and transfer the following catecholamines into separate 200-mL volumetric flasks: 10.0 mg epinephrine free base (MW 183.2); 10.0 mg norepinephrine free base (MW 169.2); 12.4 mg dopamine HCl (3-hydroxytyramine HCl, MW 189.6). Dissolve and dilute to the mark with $HClO_4$, 0.1 mol/L, to give free-base concentrations of 50 mg/L. Store the stock calibrators at 4 °C. Stable for at least 6 months.
9. Catecholamine combination calibrator. Dilute 100 µL of the catecholamine stock calibrators to 100 mL with $HClO_4$, 0.1 mol/L, to give free-base concentrations of 50 µg/L. Store at 4 °C.
10. Stock internal standard, 3,4-dihydroxybenzylamine, 50 mg/L. Dissolve 16 mg 3,4-dihydroxybenzylamine hydrobromide (DHBA HBr, MW 220.1) in $HClO_4$, 0.1 mol/L. Dilute to 200 mL with $HClO_4$, 0.1 mol/L, in a volumetric flask. Store at 4 °C. Stable for at least 6 months.
    Note: The free-base concentration is calculated by multiplying the mass of the salt by the molecular weight ratio of free base to salt.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 29-1 Determination of Plasma Free Catecholamines by HPLC/EC—cont'd

For example:
(16 mg DHBA HBr)/(0.2 L perchloric acid) × (MW free base = 139)/(MW salt = 220.1) = 50 mg/L (free-base concentration)

11. Working internal standard, 3,4-dihydroxybenzylamine, 50 µg/L. Dilute 100 µL of the DHBA HBr stock internal standard (50 mg/L) to 100 mL with $HClO_4$, 0.1 mol/L. Store at 4 °C.
12. Catecholamine prerun calibrator. Dilute 500 µL of the catecholamine combination calibrator and 1000 µL of the working internal standard to 10 mL with $HClO_4$, 0.1 mol/L. Prepare fresh daily.
13. Tris buffer. Dissolve 45 g of Trizma base and 5 g Na_2EDTA in approximately 200 mL distilled water. Adjust to pH 8.6 by adding drops of concentrated HCl, 12 mol/L. Dilute to 250 mL and filter. Store at 4 °C. Stable for 2 months.
14. Water, pH 7.0. Using a pH meter, adjust approximately 500 mL of distilled water to pH 7.0 with sodium hydroxide (0.1 mol/L) or phosphoric acid (0.1 mol/L), as required. Check pH of H_2O just before use. Adjust as necessary.
15. Alumina (acid-washed aluminum oxide; Bioanalytical Systems, West LaFayette, Ind., Catalog No. CF-8010). Store tightly capped in a desiccator.
16. Mobile phase, acetonitrile-citrate mixture. Dissolve 20.59 g trisodium citrate dihydrate in 880 mL distilled water. Using a pH meter, adjust the solution to pH 6.50 ± 0.02 with H_3PO_4 as required. Add 120 mL acetonitrile and mix well. Filter the buffer mixture through a Millipore filtration device using a 0.45 Tm (Type HA) membrane filter. Release vacuum immediately after filtration is complete. Store tightly capped at room temperature.
17. HPLC column wash reagent. Using a pH meter, adjust 1 L distilled water to pH 3 with H_3PO_4 (2 mol/L) as required.

Instrumentation

A commercially available HPLC system equipped with a 15 cm × 4.6-mm (I.D.) cation-exchange silica column and an electrochemical detector is suitable.

Quality Control

Two controls are included in every run. For example, Bio-Rad Lyphochek Endocrine Control, Levels 1 and 2 (Bio-Rad Clinical Diagnostics Group, Hercules, Calif.) are reconstituted each day with distilled water and processed for immediate use. Controls are placed in an ice bath until ready to use.

Procedure

Preanalysis Check

1. Establish operating conditions of the chromatographic and detection systems. Suggested conditions are as follows:
   Flow rate: 1.1 mL/min
   Potential: 500 mV
   Sensitivity: 5 nA/V
   Chart speed: 1 cm/min
2. Inject 100 µL of the catecholamine prerun calibrator at least twice.
3. Inspect the chromatograms using the following guidelines to monitor performance of the chromatography system:
   a. Retention times are not different for the two injections. (Note: If retention times differ, reinject the calibrator as needed to confirm that the system is at equilibrium.)
   b. Epinephrine retention time is approximately 5 to 6 minutes.
   c. Epinephrine is clearly separated from the solvent front.
   d. Epinephrine peak height is 30% to 50% of full scale.
   e. All peak heights are within ±5% on repeat injection.

Sample Analysis

4. Remove patient samples (heparinized plasma) and catecholamine-free plasma from frozen storage and thaw in a 37 °C water bath. Mix well. Centrifuge the patient samples for 5 minutes. Place all samples in an ice bath until ready to use.
5. Prepare control samples as noted under Controls.
6. Pipette 4.0 mL of each patient sample and control into labeled 96 × 16.8-mm extraction tubes.
7. Pipette 20, 40, and 80 µL of the catecholamine combination calibrator into labeled tubes containing 4.0 mL of the catecholamine-free plasma.
8. To all tubes add 80 µL of the working internal standard solution (50 µg/L).
9. Using a measuring spoon, transfer two level spoonfuls of alumina (about 60 to 80 mg) to each tube.
10. Add 2 mL Tris buffer to each tube.
11. Immediately cap each tube and shake vigorously for 10 minutes using the mechanical shaker.
12. Centrifuge the tubes for 2 minutes at 3000 rpm.
13. Without disturbing the alumina pellet, remove the supernatant from each tube using a vacuum aspirator connected to a vacuum trap.
14. Using a squirt bottle, add about 1 mL of pH 7 adjusted water to each tube. Vortex mix the tubes for 15 seconds. (Note: To ensure thorough washing of the alumina, no portion of the alumina pellet should remain on the bottom of the tube during mixing.)
15. Centrifuge the tubes for 2 minutes at 3000 rpm.
16. Carefully remove as much supernatant liquid as possible without disturbing the alumina pellet. (Note: This step is critically important!)
17. Wash the alumina again by repeating steps 14, 15, and 16.
18. Add 400µL of $HClO_4$, 0.1 mol/L, to each tube. Vortex mix for 30 seconds. Allow to stand for 5 minutes and then vortex mix for 30 seconds. (Note: Thorough mixing is important to ensure good recovery of the catecholamines.)
19. Centrifuge each tube for 2 minutes at 3000 rpm. (Note: Do not allow the supernatant extract to remain in contact with the alumina for more than 30 minutes. Otherwise, degradation of the catecholamines can result.)
20. Using a glass Pasteur pipette, carefully transfer the supernatant to a storage vial. At this time, samples may be stored at 4 °C for up to 24 hours before injection into the HPLC system. (Note: Extracts should not be injected until the baseline has been established. Check regularly for baseline shifts, and rezero the output of the detector as necessary.)
21. Introduce 100µL of each standard, patient specimen, and control into the HPLC column. (Note: The remaining extract can be used for dilutions as required.)

Chromatogram

Figure A29-1 shows a representative chromatogram of catecholamines extracted from plasma control.

Continued

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 29-1 Determination of Plasma Free Catecholamines by HPLC/EC—cont'd

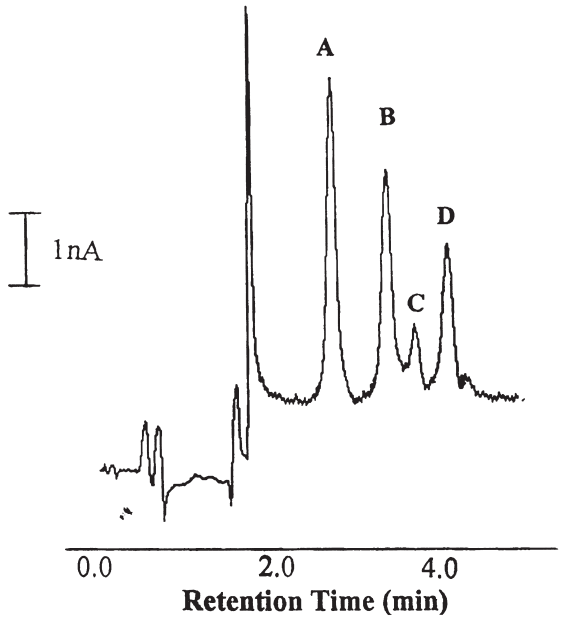

Figure A29-1 Representative chromatogram of catecholamines extracted from a plasma control sample. Epinephrine (A), dopamine (B), and 3,4-dihydroxybenzylamine (D) retention are identified on the chromatogram.

Calculations

1. Check sample identification of each chromatogram to ensure proper labeling.
2. Identify catecholamine and internal standard peaks by relative retention times.
3. For manual integration, use a ruler to draw a line under all peaks. Identify the baseline points (deepest valleys) and draw lines that connect these baseline points. (Note: Disregard small valleys between partially fused peaks.)
4. For each sample, measure the peak heights to the nearest 0.1 cm. Record results on the appropriate worksheet as the example shows below:

Calibrating Compound	Retention Time, min	Peak Heights, cm
Epinephrine	5.4	9.0
Norepinephrine	6.7	6.1
Dopamine	7.4	1.8
Internal standard	8.2	4.3

(Note: The analyst should verify that the internal standard (IS) peak height for each patient sample or control is >75% of the IS peak height for the extracted calibrator.)

5. Calculate ratio of peak heights (peak height of catecholamine/peak height of internal standard) for each patient sample, control, and calibrator.
6. Establish a calibration curve by plotting the peak height ratio of each catecholamine calibrator on ordinate versus concentration on abscissa (250, 500, and 1000 pg/mL).
7. Calculate concentrations of unknown catecholamines as follows:
   a. Estimate a linear regression line for the data set and calculate unknown concentrations.
   b. Manual calculation:

$$CAT = U/S \times 50 \times 0.04/4.0 \times 1000$$

where: CAT = unknown catecholamine concentration (pg/mL)
U = unknown catecholamine peak height ratio
S = peak height ratio for 500 pg/mL calibrator determined from a calibration curve
50 = free-base concentration of catecholamine combination calibrator (50 µg/L)
0.04 = volume of catecholamine calibrator applied to alumina (mL)
4.0 = volume of patient sample or control applied to alumina (mL)
1000 = conversion factor (µg/L to pg/mL)

8. Linearity:
   norepinephrine: 15–2000 pg/mL
   epinephrine: 15–2000 pg/mL
   dopamine: 15–2000 pg/mL
   When calculated values exceed these limits, the patient extract is diluted with $HClO_4$, 0.1 mol/L, and the analysis repeated started at procedure step 21.

Comments

1. When calculated values are less than the linearity limits listed previously, results are reported as <15 pg/mL.
2. Labetalol (Normadyne and Trandate) interferes chemically with this assay.

Reference Intervals

Norepinephrine

	pg/mL (pmol/L)
Supine (30 min)	110–410 (650–2423)
Sitting (15 min)	120–680 (709–4019)
Standing (30 min)	125–700 (739–4137)

Epinephrine

	pg/mL (pmol/L)
Supine (30 min)	<50 (<273)
Sitting (15 min)	<60 (<328)
Standing (30 min)	<90 (<491)

Dopamine

	pg/mL (pmol/L)
Supine (30 min)	<87 (<475)
Sitting (15 min)	<87 (<475)
Standing (30 min)	<87 (<475)

METHOD 29-2 Determination of Plasma Free Metanephrines by Liquid Chromatography With Electrochemical Detection

Submitted by Graeme Eisenhofer, Ph.D.
Clinical Neurocardiology Section, National Institutes of Health, Bethesda, Maryland.

Principle

This method allows measurement of picomolar plasma concentrations of normetanephrine, the O-methylated metabolite of norepinephrine; metanephrine, the metabolite of epinephrine; and methoxytyramine, the metabolite of dopamine. An initial extraction procedure serves to isolate and concentrate the low picomolar concentrations of free O-methylated amine metabolites into a purified low volume form appropriate for injection onto the HPLC apparatus. In this procedure, samples of plasma together with a known amount of internal standard and a small amount of dilute acetic acid are applied to extraction columns containing a cation exchange resin. The extraction columns are first activated by washing with methanolic potassium hydroxide to bring up the negative charges on the column matrix. The positively charged O-methylated amine metabolites are thereby selectively adsorbed onto the activated cation exchange resin. The extraction columns are then washed with dilute solutions of acetic acid, ammonium phosphate, and water. The metabolites are eluted from extraction columns using ammoniacal methanol, which is then dried down and the residue reconstituted in a minimum volume of dilute acetic acid ready for measurement by liquid chromatography with coulometric detection.

Measurement by HPLC involves separation of the O-methylated amines using a C_{18} reversed-phase HPLC column followed by their ordered post column detection by coulometry. Mobile phase is pumped through the autosampler and HPLC column using a solvent delivery system that provides a continuous, pulse-free flow of mobile phase through the system. Separation on the HPLC column is facilitated by hydrophobic and ionic interactions between components of the C_{18} analytical column stationary phase, mobile phase, and O-methylated amines.

The mobile phase provides an "adjustable" vehicle for passage of the analytes of interest through the analytical column to the coulometric detector. Adjustments to the composition of the mobile phase, specifically the pH and concentrations of octane sulfonate and acetonitrile, allow fine-tuning of the separation of analytes of interest on the analytical column. The negatively charged octane sulfonate ion-pairing reagent binds to positively charged O-methylated amines. In turn, interactions of the hydrophobic carbon chain of the octane sulfonate molecules with the hydrophobic C_{18} analytical column matrix lead to retention of the positively changed analytes of interest on the HPLC column. Thus by varying the octane sulfonate concentration, the retention of positively charged analytes of interest may be altered in relation to other uncharged or changed species or potentially interfering compounds. Subtle changes in the pH of the mobile phase (i.e., between pH 3.15 and 3.40) provide a further mechanism for altering the charge, and thus the retention on the analytical column of O-methylated amines or contaminating substances. Variations in the concentration of acetonitrile organic phase provide a further means to adjust the retention of O-methylated amines and potentially interfering substances by modifying the overall extent of hydrophobic interactions. Further changes to retention can be facilitated by alterations to the column temperature. Changes to the composition of the mobile phase may be made when there is need for adjustment of retention times of O-methylated amines and interfering compounds.

Mobile phase eluting from the outlet of the analytical column and containing the O-methylated amines then passes through a triple electrode coulometric system, consisting of a conditioning cell and an analytical cell connected to the Coulochem detector. The functions of the electrochemical detection system are the detection and quantification of the O-methylated amines after their separation and elution on the analytical column. The first electrode in the conditioning cell is set to an oxidizing potential to screen out irreversibly oxidized contaminating species that may otherwise interfere with subsequent detection by a reducing potential at the third analytical electrode. The hydroxyl groups on the amine metabolites are normally in the reduced state, but the compounds are reversibly oxidized and reduced so that measurement by reduction at the analytical cell is possible after the compounds are oxidized at the first electrode in the conditioning cell. Outputs from the third electrochemical cell at a reducing potential are generated as chromatographic recordings suitable for subsequent analysis. Sample concentrations are calculated from peak heights of the amine metabolites relative to those of calibrators and corrected according to the procedural recovery of an internal standard.

Specimen Collection and Storage

Patients should be in the supine position for at least 20 minutes before and during collection of blood samples. To avoid the acute effects of the stress of venipuncture, it is preferable to use an indwelling IV placed in a vein at least 20 minutes before the blood sample is drawn. Ten 1-milliliter samples of blood should be drawn into a evacuated collection tubes containing heparin in any form or EDTA as an anticoagulant.

The O-methylated amine metabolites are not stable in whole blood at room temperature. Therefore samples of blood should be placed on ice and centrifuged (preferably at 4 °C) to separate the plasma within 2 hours of collection. Aliquots of plasma should be stored at −70 °C or colder until analysis. Samples requiring shipping should be kept frozen using suitable amounts of dry ice packaged in styrofoam containers. The O-methylated metabolites in such samples are stable for up to 5 years.

Analytical Interferences

Acetaminophen produces known interference with assays of plasma free metanephrines. The patient should therefore not have taken acetaminophen in any form (e.g., Tylenol, Excedrin, and combined cold medications) for at least 5 days before the blood sample is drawn. Apart from acetaminophen there are no other established causes of direct analytical interference from common over the counter or prescribed medications (see below). However, occasional co-chromatographing or interfering peaks do occur from unknown substances in plasma of either endogenous or exogenous origin. These interferences can be particularly prevalent after meals or in patients with renal insufficiency. Therefore to minimize the appearance of chromatographic interferences from dietary substances, samples of blood should be obtained after an overnight fast (water and decaffeinated soft drinks are permissible).

METHOD 29-2 Determination of Plasma Free Metanephrines by Liquid Chromatography With Electrochemical Detection—cont'd

Reagents

1. Calibrators: DL-normetanephrine HCl, DL-metanephrine HCl, DL-methoxytyramine HCl, 4-hydroxy-3-methoxybenzylamine HCl (all analytical grade); 4-hydroxy-3-ethoxyphenylethanolamine, special NIH synthesis. Store refrigerated. Expiration—3 years.
2. Prepare all calibrators to contain 1 mg/mL stock calibrator (free base) solutions in 0.2 mol/L acetic acid then dilute each of them to separate 100 ng/mL (normetanephrine, metanephrine, and methoxytyramine) or 200 ng/mL (internal standards) working standard solutions in 0.2 mol/L acetic acid. Store as aliquots in 1.5 mL Eppendorf tubes at −70 °C to −80 °C. Expiration—2 years.
3. Mobile phase:
   a. Acetonitrile, HPLC grade (no fixed source). Store at room temperature. Expiration—3 years.
   b. 1-Octane sulfonic acid, ultrapure grade (Sigma O 0133). Store at room temperature. Expiration—3 years.
   c. Phosphoric acid, HPLC grade (no fixed source). Store at room temperature. Expiration—3 years.
   d. Sodium phosphate monobasic ($NaH_2PO_4 \cdot H_2O$), analytical grade (no fixed source). Store at room temperature. Expiration—3 years.
   e. Ethylenediamine-tetraacetic acid disodium salt: Dihydrate (EDTA), analytical grade (Sigma ED2SS) Store at room temperature. Expiration—3 years.
   f. Mobile phase stock solution: Add to a clean 1 L bottle 138 g of sodium phosphate monobasic, 1.28 g of octane sulfonate, and 100 mg EDTA. Dilute to 1 L with deionized water and stir thoroughly to dissolve. Store at room temperature. Expiration—6 months.
   g. Mobile phase working solution: Add to a clean 1 L bottle, 100 mL of mobile phase stock solution and 50 to 90 mL of HPLC grade acetonitrile (75 mL is often most appropriate for a new column—see note below). Dilute to 950 mL with milli-Q water and adjust pH with stirring to an appropriate point between pH 3.15 and pH 3.45 with HPLC grade phosphoric acid (a pH of 3.25 is a most appropriate point to start with a new column—see note below). Dilute to a final volume of 1 L with milli-Q water and Millipore filter through a 0.22 µm type of GV (Millipore) filter under vacuum. Decant to a clean bottle and pump through HPLC system. Expiration—7 days or sooner depending on background current.
4. Ion exchange extraction reagents:
   a. Bond Elut LRC Accucat Cation Exchange columns with 200 mg packing (Varian P/N 1228-2005, Analytichem International, Harbor City, Calif.) Store at room temperature. Expiration—1 year.
   b. One percent KOH in methanol: Dissolve 5.0 g KOH (MW 56) in 500 mL of methanol or mix 89 mL 1 mol/L methanolic potassium hydroxide solution with 411 mL methanol. Store at room temperature. Expiration—6 months.
   c. Ten mmol/L acetic acid in methanol: Add 570 µL glacial acetic acid to 1000 mL of deionized H_2O (10 mmol/L acetic acid). Mix together 900 mL 10 mmol/L acetic acid with 100 mL methanol. Store at room temperature. Expiration—6 months.
   d. Ammonium phosphate 10 mmol/L, pH 8.5: Dissolve 1.15 g monobasic ammonium phosphate (MW 115.03) in 800 mL deionized H_2O. Adjust the pH to 8.5 with 5% ammonium hydroxide (5 mL ammonium hydroxide in 95 mL H_2O). Adjust volume to 1 L with deionized H_2O and add 0.05 g EDTA. Store at room temperature. Expiration—6 months.
   e. Ten percent ammonium hydroxide/methanol solution (1:3): Add together 90 mL deionized H_2O, 10 mL concentrated ammonium hydroxide solution, and 300 mL HPLC grade methanol. Made fresh on day of use. Expiration—1 day.
   f. Acetic acid, 0.2 mol/L: Dilute 12 mL of glacial acid with milli-Q water to 1 L. Store at room temperature. Expiration—1 year.

HPLC Instrumentation

1. Isocratic solvent delivery system (HPLC pump): Should be relatively pulse free (e.g., Waters model 515, Waters Chromatography, Milford, Mass.)
2. Autosampler: Should be refrigerated and capable of delivering at least 90% of a 100 µL sample onto the analytical column (Waters 717 plus autosampler is recommended, Waters Chromatography, Milford, Mass.).
3. Analytical column: 5-µm particle size 4.6 × 250 mm C_{18} reversed-phase column (LUNA, P/N 00G4252-EO, Phenomenex, Torrance, Calif.).
4. Guard column (P/N KJO–4282, Phenomenex, Torrance, Calif.)—C_{18} inserts changed before each run.
5. Column temperature control unit: Required for maintaining constant column temperature (column cooler 250, Cera Inc., Baldwin Park, Calif.).
6. Coulometric detector: (Model 5100A or Model 5200A Coulochem electrochemical detector, Environmental Sciences Associates Inc., Chelmsford, Mass.).
7. Multiple electrode system (Model 5021 conditioning cell and Model 5011 analytical cell, Environmental Sciences Associates Inc., Chelmsford, Mass.).
8. Data acquisition hardware and software system.

Extraction Equipment

1. Vacuum manifold for placement of extraction columns and diversion of solutions to waste or to collection tubes (Vac-Elut SPS 24, Analytichem International, Harbor City, Calif.).
2. Vacuum concentrator for drying down and concentration of ammoniacal methanol extracts in glass culture tubes. Should include centrifugation to avoid loss of sample from glass culture tubes (SVC200H Speed Vac Concentrator and RVT 4104 Refrigerated Vapor Trap, both from Thermo Savant, Holbrook, N.Y.).

Quality Control

Each extraction and HPLC run should include a water blank, a QC sample (normal QC) and 1 spiked QC sample (high QC) at the beginning of the run. This should be followed by the samples to be assayed. A second set of QC samples should be included in the middle and at the end of the run depending on the expected duration of the run.

Procedures

Extraction Procedure

1. Remove plasma samples and calibrators from freezer and thaw at room temperature. Spin thawed plasma at 3000 g for 10

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 29-2 Determination of Plasma Free Metanephrines by Liquid Chromatography With Electrochemical Detection—cont'd

minutes to pellet fibrin and other particulate matter (Note: It is essential that samples are free of particulate matter for their efficient passage through extraction columns).
2. Number extraction columns, 13 × 100 mm culture tubes, and sample sheet according to the sequence of samples to be extracted and run on the HPLC.
3. Wash extraction columns with 5 mL NH_4OH: methanol under light vacuum (1 to 5 mmHg). Do not allow columns to dry out.
4. Activate columns with 2 mL KOH: methanol under reduced vacuum (1 to 5 mmHg). Again do not allow columns to dry out.
5. Wash columns with 2 mL deionized H_2O under reduced vacuum (1 to 5 mmHg). Again do not allow columns to dry out.
6. Add to columns 1 mL deionized H_2O, 70 µL of 0.2 mol/L acetic acid, then the water (for blank) or plasma sample (2 mL) followed by 20 µL of internal standard solution. Pass the whole solution slowly through the column under reduced pressure (Elution time should be between 2 and 5 minutes).
7. Wash columns with 2 mL acetic acid: methanol under reduced vacuum and dry the column out by increasing the vacuum to −20 mmHg for 2 minutes.
8. Wash columns with 2 mL ammonium phosphate solution under reduced vacuum.
9. Wash columns with 2 mL deionized H_2O under reduced vacuum. Elute all H_2O.
10. Rotate the vacuum manifold to collect samples into the numbered 13 × 100 mm glass culture tubes and check for correct positioning of all needles.
11. Elute samples into culture tubes with 2 mL of NH_4OH: methanol. Use gravity and finally vacuum to elute all the NH_4OH: methanol.
12. Dry the sample down using a vacuum concentrator.
13. Dissolve the residue in 150 µL of 0.2 mol/L acetic acid and inject 140 µL onto the HPLC system.

High-Performance Liquid Chromatography

1. Establish optimal operating conditions of the chromatographic and detection systems. Suggested conditions are as follows:

Flow rate:	1.0 mL/min
Conditioning cell potential:	+0.40 V (oxidization)
Analytical cell 1 potential:	+0.15 V
Analytical cell 2 potential:	−0.40 V (reduction)

2. Before the introduction of specimens onto the reversed-phase HPLC column, ensure that the background current at the detecting cell (i.e., the cell with the reducing potential) is below 0.02 µamp, that there is negligible baseline noise, and no injection artifacts or inappropriate additional chromatographic peaks upon injection of the series of calibrators. Figure A29-2 shows representative chromatograms of an injected mixture of standards (A), an extracted sample of plasma from a healthy volunteer (B), and an extracted sample of plasma from a patient with a small adrenal pheochromocytoma (C).

Comments

A distinct and important feature of the electrochemical detection used in this method is the use of a coulometric mode, which is distinct from the amperometric mode of electrochemical detection used in many other procedures. Most commercially available electrochemical detectors feature glassy carbon or wall jet cells that usually enable charge transfer of only 1% to 5% of the analyte that passes by or across the electrode surface. Since most analytes, including catecholamines and their metabolites, are usually present in the reduced state, the charge transfer in amperometric detection generally requires oxidation. The detector required for the method described here features flow-through porous carbon cells, which allow oxidation or reduction of 100% of the analyte passing through the cell. Under these conditions of charge transfer, the electrode response is defined as coulometric as distinct from amperometric.

The advantage of coulometric detection for measurements of catecholamines and metanephrines is that these analytes can be reversibly oxidized and reduced. In contrast, for other substances, oxidation is often irreversible. A preoxidation step at the first in a series of electrodes thereby provides a mechanism to reversibly oxidize the analytes of interest while screening out potentially interfering impurities by irreversible oxidation. The reversibly oxidized analytes of interest may then be detected at a reducing potential without interference from any irreversibly oxidized impurities in the sample.

The above features of coulometric detection enable generation of much cleaner chromatograms than would otherwise be possible for measurements of plasma free metanephrines. This is particularly useful for measurements of extremely low levels of analytes, such as catecholamines and metanephrines, where potentially interfering substances are often present in the sample at much greater concentrations than the analytes of interest.

Reference Intervals

Adult Reference Intervals

The reference intervals below are determined using data from 178 normotensive and hypertensive individuals, including 100 men and 78 women, ages 18 to 72. Data were log-transformed before analysis, and upper and lower reference intervals were determined from the 95% confidence limits (i.e., 2 standard deviations above and below the geometric mean).

Analyte	Geometric Mean	Upper Reference Limit	Lower Reference Limit
Normetanephrine			
(pg/mL)	45	112	18
(nmol/L)	0.25	0.61	0.10
Metanephrine			
(pg/mL)	27	61	12
(nmol/L)	0.14	0.31	0.06

Adult Reference Intervals Adjusted for Age and Gender

The reference intervals shown below are adjusted for a significant influence of gender on plasma concentrations of metanephrine and a significant influence of age on plasma normetanephrine and total normetanephrine. Data were log-transformed before analysis, and upper and lower reference intervals were determined from the 95% confidence limits.

METHOD 29-3 Determination of Plasma Free Metanephrine and Normetanephrine by LC-MS/MS

Submitted by Ravinder J. Singh, Ph.D.
Department of Laboratory Medicine and Pathology, Mayo Clinic and Foundation, Rochester, Minn.

Principle

Free metanephrine (MN) and normetanephrine (NMN) are extracted from plasma using solid phase extraction. The concentrated eluate is analyzed using liquid chromatography-tandem mass spectrometry (LC-MS/MS) and quantified using stable isotope-labeled internal standards, d_3-metanephrine (d_3-MN) and d_3-normetanephrine (d_3-NMN). Analytes and internal standards are ionized using atmospheric pressure chemical ionization and are detected in the multiple reaction monitoring (MRM) mode using the specific transitions for m/z 180 to m/z 148, m/z 166 to m/z 134, m/z 183 to m/z 151, and m/z 169 to m/z 137, respectively.

Metanephrine and normetanephrine are the metabolites of epinephrine and norepinephrine, respectively. They are produced by the actions of the enzyme catechol-*O*-methyltransferase (COMT). The membrane-bound form of the enzyme is specifically highly expressed in pheochromocytes of the tumor. Measurements of plasma metanephrines have been found to be more sensitive than those of plasma catecholamines for the identification of patients with pheochromocytoma.

Specimen Collection and Storage

Use a 100 × 16 mm lavender stopper vacutainer containing 15 mg EDTA. Ten milliliters of blood is collected and centrifuged at 2000 rpm for 10 minutes. The plasma is removed and placed in 15 mL conical centrifuge tubes and is immediately frozen at –20 °C until time of analysis. The specimen is stored at –20 °C for short-term storage. Store at –70 °C if long-term storage is required.

Reagents

1. DL-Metanephrine HCl, Sigma Chemical Co. M-8625 (or equivalent >98% purity). Store at 2 °C to 8 °C. Stable until expiration date.
2. DL-Normetanephrine HCl, Sigma Chemical Co. N-7127 (or equivalent >98% purity). Store at 2 °C to 8 °C. Stable until expiration date.
3. d_3-Metanephrine HCl-α,α,β-d_3, Cambridge Isotope Laboratories, Inc. Store at 2 °C to 8 °C. Stable until expiration date.
4. d_3-Normetanephrine HCl-α,α,β-d_3, Medical Isotopes, Inc., Pelham, NH. Store at 2 °C to 8 °C. Stable until expiration date.
5. Oasis TM HLB 1 cc (30 mg) extraction cartridges, Waters WAT094225. Store at room temperature. Stable until expiration date.
6. Charcoal Stripped Serum, SeraCare, Inc. HS-230. Store at 2 °C to 8 °C. Stable until expiration date.
7. Methanol (HPLC grade), EM Science MX0488-1 (4L). Store at room temperature. Stable until expiration date.
8. Water, HPLC Grade, Fisher Scientific W5-4. Store at room temperature. Stable until expiration date.
9. Formic acid, Sigma F-0507. Store at room temperature. Stable until expiration date.
10. Trifluoroacetic acid (TFA), Pierce 28901. Store at room temperature. Stable until expiration date.
11. Ammonium acetate, Sigma A-7330. Store at 2 °C to 8 °C. Stable until expiration date.
12. Acetonitrile (HPLC grade), Aldrich 27,071-7 (2 L). Store at room temperature. Stable until expiration date.
13. Analytical stock calibrator solution (1.0 mg/mL). Weigh out 11.8 mg of metanephrine HCl and 12.0 mg of normetanephrine HCl. Transfer to a 10 mL volumetric flask and add RO H_2O (water processed by reverse-osmosis) to volume. Store at –20 °C. Stable 12 months.
14. Analytical working dilution I (10 µg/mL). Add 100 µL stock calibrator to 9.9 mL RO H_2O. Store at 2 °C to 8 °C. Stable 3 months.
15. Analytical working dilution II (100 ng/mL). Add 100 µL analytical working I to 9.9 mL RO H_2O. Store at 2 °C to 8 °C. Stable 3 months.
16. Analytical working dilution III (10 ng/mL). Add 1.0 mL analytical working II to 9.0 mL RO H_2O. Store at 2 °C to 8 °C. Stable 3 months.
17. Analytical working dilution IV (1 ng/mL). Add 1.0 mL analytical working III to 9.0 mL RO H_2O. Store at 2 °C to 8 °C. Stable 3 months.
18. Calibrators 1 to 6. Pipette stripped serum and analytical calibrator (see chart) into 12 × 75 tubes; store at –20 °C.

METHOD 29-3 Determination of Plasma Free Metanephrine and Normetanephrine by LC-MS/MS—cont'd

Calibrator	Concentration Metanephrine	Concentration Normetanephrine	Volume Analytical Stripped Serum	Volume Analytical Std IV (1 ng/mL)	Volume Analytical Std III (10 ng/mL)
1	0.25 nmol/L	0.27 nmol/L	1 mL	50 µL	—
2	0.5 nmol/L	0.54 nmol/L	1 mL	100 µL	—
3	1.0 nmol/L	1.08 nmol/L	1 mL	200 µL	—
4	2.5 nmol/L	2.7 nmol/L	1 mL	—	50 µL
5	5.0 nmol/L	5.4 nmol/L	1 mL	—	100 µL
6	10.0 nmol/L	10.8 nmol/L	1 mL	—	200 µL

1. Internal stock standard solution (1.0 mg/mL). Weigh out 11.8 mg of d_3-metanephrine HCl and 12.0 mg of d_3-normetanephrine HCl. Transfer to a 10 mL volumetric flask and add RO H_2O to volume. Store at −20 °C. Stable 12 months.
2. Internal working dilution I (10 µg/mL). Add 100 µL stock standard to 9.9 mL RO H_2O. Store at 2 °C to 8 °C. Stable 3 months.
3. Internal working dilution II (100 ng/mL). Add 100 µL internal working I to 9.9 mL RO H_2O. Store at 2 °C to 8 °C. Stable 3 months.
4. Internal working dilution III (10 ng/mL). Add 1.0 mL internal working II to 9.0 mL RO H_2O. Store at 2 °C to 8 °C. Stable 3 months.
5. Mobile phase: 40/60 (v/v) acetonitrile/HPLC grade water, 1.5 mmol/L ammonium acetate, 0.06% formic acid, 0.04% trifluoroacetic acid. Weigh out 120 mg ammonium acetate and transfer to a 1 L flask. Add 600 mL RO H_2O and 400 mL acetonitrile. Mix with magnetic stir bar until in solution. Add 60 µL formic acid and 40 µL trifluoroacetic acid. Store at room temperature. Stable 2 weeks.
6. Injector rinse solution: 75/25 (v/v) methanol/RO H_2O. Combine 750 mL methanol and 250 mL of RO H_2O.

Consumables

1. Plastic tubes, 13 × 75 mm, Sarstedt.
2. Disposable culture tubes, 10 × 75 mm, Fisher Scientific 14-961-25.
3. Pipette tips, 1000 µL and 200 µL, Continental Lab Products 2167, 2007.
4. Disposable plastic transfer pipettes, Fisher Scientific 13-711-7.
5. Autosampler vials, National Scientific Co., Target DP Catalog No. C4000-1, or Fisher Scientific minivials 0.2 mL Catalog No. 0334064 with snap-it-seal cap Catalog No. 0337749.
6. Caps, National Scientific Co., DP blue cap & TS septa, Catalog No. C4000-54B.
7. Inserts, National Scientific Co., 0.3 mL, Catalog No. C4010-630.

Instrumentation

1. Gilson Pipetman pipettes, 1000 µL adjustable, 200 µL adjustable
2. Eppendorf repeater pipette
3. Supelco vacuum manifold
4. PE Sciex API 3000 LC-MS/MS with Atmospheric Pressure Chemical Ionization Source
5. PE Series 200 isocratic LC pump
6. PE Series 200 LC autosampler with 100 position sample tray insert
7. Analyst software 1.1 P/N 027232A
8. HPLC column: LUNA CN, 15 cm × 4.6 mm, 5 µm, Phenomenex
9. Guard column: Security Guard CN, 2 cm × 2.1 mm, 5 µm, Phenomenex
10. Offline HPLC pump for flushing column after analysis

Calibration

The calibration uses a six point extracted calibrator curve over a concentration range of 0.25 to 10 nmol/L. Calibration curves are generated with each assay. The Analyst software package calculates the area counts and plots a calibration curve for the analyte/IS area count ratio versus analyte/IS concentration ratio.

Remove calibrator set from freezer and let thaw about 30 minutes. Follow sample extraction procedure.

Controls

Analysis of spiked plasma controls (low, medium, and high) is performed with each assay. The spiked plasma control pools are made by adding calibrators to plasma pools so that the final concentrations of MN and NMN are approximately 0.3, 0.6; 1.0, 2.0; and 2.0, 4.0 nmol/L, respectively. The pool is assayed to verify the appropriate concentration and further diluted if necessary. When the desired level is obtained, it is mixed well and aliquoted into plastic tubes and kept at −20 °C.

Tolerance limits are established by assaying each pool level 20 times over multiple days in conjunction with the current pools. Values are recorded using Levy-Jennings control charts and monitored for trends and shifts. Controls that are not acceptable will result in repeating selected values or the entire assay. Controls and curve parameters are used as a measure of assay acceptability with final interpretation made by the laboratory supervisor or director. General QC rules in effect are:

All controls within ± 2 SD limits:	Release results
One control exceeds ± 2 SD limits:	First time, release results Subsequent occurrences, take corrective action
One control exceeds ± 3 SD limits:	Take corrective action
Two or more controls exceed ± 2 SD limits:	Take corrective action

Corrective action may include: (1) evaluating results, including repeats and linearity; (2) evaluating control pool and/or reagents; (3) repeating the assay; or (4) notifying supervisor or lead personnel.

Procedure

Sample Preparation

1. Invert plasmas to mix, and place 1.0 mL of patient or control plasma in a labeled 12 × 75 mm Sarstedt tube.
2. Add 50 µL of internal standard working dilution III to each tube using an Eppendorf repeater pipette.

METHOD 29-3 Determination of Plasma Free Metanephrine and Normetanephrine by LC-MS/MS—cont'd

Solid Phase Extraction

1. Load Oasis HLB SPE cartridges on to the Supelco vacuum manifold and pull vacuum at 5 in Hg for all steps. Precondition the cartridges with 1 mL methanol followed by 1 mL RO H_2O.
2. Add the plasma/IS mixture with a plastic disposable transfer pipette.
3. Wash with 2 mL of RO H_2O.
4. Place an empty 12 × 75 mm disposable culture tube in the manifold rack for each SPE cartridge. Place manifold rack into manifold and verify that all tubes are in line with a SPE connection. Elute MN and NMN with 1 mL methanol. Discard Oasis cartridges after each use.
5. Evaporate the eluate in a Zymark TurboVap LV evaporator at 45 °C and 15 psi for 20 minutes.
6. Reconstitute with 50 µL methanol and transfer to autosampler vials. Refrigerate until analysis. Extracted specimens are stable for up to 3 days.

LC-MS/MS

1. Build the sample batch using the Analyst software and inject the preview standard to insure that the instrument is operating properly and that the chromatography is resolving the peaks of interest. (See API 3000 Tandem Mass Spectrometer Operating Procedure.)
2. Continue building the load and start the run.

Project name:	PMET
Acquisition method:	PMET
Flow	1.2 mL/min
Inj volume	30 µL
Run time	8.0 min
Pre/Postinjection flushes	0/5

3. Mobile phase: 40/60 (v/v) acetonitrile/HPLC grade water 1.5 mmol/L ammonium acetate. 0.06% formic acid, 0.04% trifluoroacetic acid. HPLC column: LUNA CN, 15 cm × 4.6 mm, 5 µm, Phenomenex Guard column: Security Guard CN, 2 cm × 2.1 mm, 5 µm, Phenomenex.

MS/MS Parameters:

Parameter	MN	d_3-MN	NMN	d_3-NMN
MRM pairs	180.0/ 148.0	183.3/ 151.0	166.2/ 134.0	169.2/ 137.0
Dwell times	500	500	500	500
Nebulizer gas (NEB)	15			
Curtain gas (CUR)	7			
Collision gas (CAD)	4			
Nebulizer current (NC)	3			
Temperature (TEM)	500			
Declustering potential (DP)	50 V			
Focusing potential (FP)	175 V			
Entrance potential (EP)	10 V			
Collision energy (CE)	25 V			
Collision cell exit potential (CXP)	2 V			

After analysis is complete, flush columns with 50/50 acetonitrile/water at 1 mL/min for 30 minutes. This will help to extend the column life. This can be performed with an off-line HPLC pump.

Calculations

Results are automatically calculated by the LC-MS/MS software and printed as nmol/L plasma. If a volume other than 1 mL plasma is used, the value should be edited appropriately. For example: if 500 µL is used, the final result should be multiplied by 2.

Reference Intervals

Metanephrine:	<0.50 nmol/L
Normetanephrine:	<0.90 nmol/L

Interpretation

Elevated results may indicate pheochromocytoma. Results may also be mildly elevated because of hypertension.

Conversion factors:
1 nmol/L MN = 0.20 ng/mL MN
1 ng/mL MN = 5 nmol/L MN
1 nmol/L NMN = 0.18 ng/mL NMN
1 ng/mL NMN = 5.6 nmol/L NMN

Procedural Notes

The organic solvents used in the extraction and mobile phases are flammable and give off toxic fumes; they should be handled with care and used in an exhaust hood. Use eye protection when working with acids or bases.

Handle all patient specimens as potentially infectious. Formal procedures for biological and chemical safety can be found in the Laboratory Safety Manual.

1. Metanephrine precision:

	Within Run			Between Run		
N	20	20	19	45	71	54
Mean	0.25	1.2	2.3	0.59	1.2	2.1
SD	0.03	0.1	0.1	0.07	0.1	0.2
CV	10.3%	5.1%	4.9%	12.5%	7.3%	7.7%

2. Normetanephrine precision:

	Within Run			Between Run		
N	20	20	19	45	71	54
Mean	0.70	2.2	2.7	0.59	1.9	2.8
SD	0.05	0.1	0.1	0.06	0.2	0.4
CV	7.5%	5.3%	4.5%	10.0%	8.8%	13.4%

3. Functional sensitivity: MN: N = 20, mean = 0.15, SD = 0.01, CV = 9.5%
   NMN: N = 20, mean = 0.34, SD = 0.02, CV = 5.0%
4. Recovery: Three different levels of calibrator were spiked into four different plasma specimens. The mean recoveries relative to the internal standard were 99% and 105% with ranges of 89% to 110% and 96% to 119% for MN and NMN, respectively. Absolute recovery from the extraction averaged 72% for MN and 60% for NMN.
5. Linearity: Elevated plasma samples were serially diluted with water and extracted separately to determine linearity. Results showed good linearity between 10.6 and 0.3 nmol/L for MN, and 28 to 0.4 nmol/L for NMN. Results greater than the highest calibrator (10 nmol/L) will be reextracted using 1:10 dilution with RO H_2O.

METHOD 29-3 Determination of Plasma Free Metanephrine and Normetanephrine by LC-MS/MS—cont'd

6. Correlation: A comparison between the Mayo LC-MS/MS method (Y) and the Mayo HPLC-EC method (X) was performed. Linear regression results are indicated below.

	N	Slope	Y-intercept	Correlation Coefficient
Metanephrine (nmol/L)	92	0.87	0.05	0.95
Normetanephrine (nmol/L)	132	0.90	−0.06	0.93

7. Reference intervals: An independent study was conducted using healthy volunteers to obtain a reference interval for the LC-MS/MS method. Results matched the existing reference intervals for the HPLC-EC method.
8. Carryover: There are no problems due to carryover on the LC-MS/MS. Reuse of Oasis cartridges was not assessed.
9. Sample stability: MN and NMN in EDTA plasma are stable when refrigerated up to 1 week or when frozen and thawed one time.

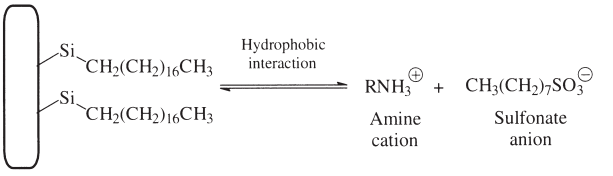
METHOD 29-4 Determination of Urinary Free Catecholamines by HPLC/EC



Submitted by Ronald J. Whitley, Ph.D. Department of Pathology and Laboratory Medicine, College of Medicine, University of Kentucky Medical Center, Lexington, Ky.

Principle

After protein precipitation with perchloric acid, an aliquot of a 24-hour urine collection (preserved in acid) is first applied to a weak-acid cation-exchange resin. Unconjugated catecholamines are selectively adsorbed at pH 6.5 and then eluted with dilute boric acid (pH 4.0). An intermediate water wash removes interfering urine impurities. Subsequent resolution of the individual catecholamines is achieved by reversed-phase, paired-ion HPLC under optimized isocratic conditions. Alkyl-bonded silica is used as the nonpolar stationary phase, and an organic/aqueous buffer mixture (pH 2.8) is used as the polar mobile phase. To enhance the affinity of the polar catecholamines for the hydrophobic stationary phase, an ion of opposite charge (octyl sodium sulfonate) is also included in the mobile phase. This "counter-ion" is capable of forming uncharged ion pair conjugates with catecholamine cations before partitioning into the lipophilic stationary phase:

This separation mechanism may also be described by postulating that the counter-ion itself partitions into the stationary phase with its ionic groups oriented at the surfaces:

The reversed-phase column then has the physical characteristics of a conventional ion-exchange resin.

A thin-layer, glassy carbon or carbon-paste working electrode, in conjunction with a silver-silver chloride reference electrode and a stainless steel auxiliary electrode, is used as the amperometric detection system. As shown earlier, each catecholamine passing through the detector cell undergoes a rapid two-electron oxidation at a fixed potential to form an o-quinone. The resulting current is converted to a voltage signal and monitored as a function of time. At a constant temperature and flow rate, this oxidation current is directly proportional to the concentration of the analyte.

Catecholamine reference materials that have been previously checked for purity are used to calibrate the system on the basis of

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 29-4 Determination of Urinary Free Catecholamines by HPLC/EC—cont'd

peak heights and retention times. To calculate sample concentrations, peak height ratios relative to the internal standard (dihydroxybenzylamine) for unknowns are compared with those of the calibrations.

Specimen Collection and Storage

All antihypertensive medications should be withheld from the patient for at least 2 days before and during specimen collection. If the patient cannot be completely removed from a drug regimen, the test may still be performed as long as the results are evaluated with an understanding of the expected physiological response to the drug or drugs.

A complete 24-hour urine sample is collected in a gallon jug containing 10 mL hydrochloric acid (HCl), 6 mol/L, as a preservative. The specimen should be refrigerated during collection. The total urine volume is measured and recorded; a 100-mL aliquot is stored in the refrigerator until the test is performed, or may be frozen and stored indefinitely.

Reagents

1. Perchloric acid ($HClO_4$), 72%, analytical grade.
2. Phosphoric acid (H_3PO_4), 85%, analytical grade.
3. Sodium phosphate (Na_2HPO_4), 10 mmol/L. Dissolve 1.42 g anhydrous Na_2HPO_4 in distilled water to final volume of 1 L. Stable at 4 °C for 3 months.
4. Potassium phosphate (KH_2PO_4), 10 mmol/L. Dissolve 1.36 g KH_2PO_4 in distilled water to final volume of 1 L. Stable at 4 °C for 3 months.
5. Phosphate buffer, 10 mmol/L, pH 6.5. Mix 32 mL Na_2HPO_4 (10 mmol/L) and 68 mL KH_2PO_4 (10 mmolL) to give 100 mL of a phosphate buffer, pH 6.5. Stable at 4 °C for 3 months.
6. Disodium EDTA (Na_2EDTA), 2.7 mmol/L. Dissolve 1 g Na_2EDTA in 1 L distilled water. Stable at room temperature for 3 months.
7. Sodium hydroxide (NaOH), 0.5 mol/L. Dissolve 20.0 g NaOH in distilled water and dilute to 1 L. Store tightly capped. Prepare monthly.
8. Boric acid (H_3BO_3), 0.65 mol/L. Dissolve 40 g H_3BO_3 in 800 mL distilled water. Warm in a 50 °C water bath to aid dissolution. Allow to cool and dilute to 1 L with water. Store at room temperature and prepare every 2 weeks.
9. Catecholamine stock calibrator. Weigh and transfer the following catecholamines to a 500-mL volumetric flask: 30.7 mg norepinephrine bitartrate monohydrate (MW 346.3), 9.1 mg epinephrine bitartrate (MW 333.3), and 55.8 mg dopamine HCl (MW 189.6). Dissolve and dilute to the mark with $HClO_4$, 0.1 mol/L, to give the following free-base concentrations: norepinephrine, 30 mg/L; epinephrine, 10 mg/L; and dopamine, 90 mg/L. Store the stock calibrator at 4 °C. Stable for at least 6 months.
   Note: Free-base concentrations are calculated by multiplying the mass of the catecholamine salt by the molecular weight ratio of free-base to salt. For norepinephrine:
   (30.7 mg norepinephrine bitartrate)/(0.5 L perchloric acid) × (MW free-base = 169.2)(MW salt = 346.3) = 30 mg/L (free-base concentration)
10. Internal standard, 3,4-dihydroxybenzylamine, 10 mgL. Dissolve 8 mg of 3,4-dihydroxybenzylamine hydrobromide (MW 220.1) in perchloric acid, 0.1 mol/L. Dilute to 500 mL with $HClO_4$, 0.1 mol/L, in a volumetric flask to give a free-base concentration of 10 mg/L. Store at 4 °C. Stable for at least 6 months.
11. Catecholamine working calibrator. Add 50 µL of the catecholamine stock calibrator and 50 µL of the internal standard solution to 7.0 mL H_3BO_3, 0.65 mol/L. Prepare fresh daily.
12. Methanol, spectrograde.
13. Sodium octyl sulfate.
14. Phosphoric acid, 0.1 mol/L. Dilute 6.9 mL H_3PO_4 (85%) to 1 L with distilled water. Store at room temperature.
15. Mobile phase, methanol/phosphate buffer (10:90). Dissolve 21.5 g KH_2PO_4, 74 mg Na_2EDTA, and 100 mg sodium octyl sulfate in 1 L distilled water. Add 3.3 mL H_3PO_4 (85%) and dilute to 2 L with distilled water. Buffer is phosphate, 0.1 mol/L, pH 2.8; octyl sodium sulfate, 50 mg/L; and Na_2EDTA, 0.1 mmol/L. Filter the buffer through a Millipore filtration apparatus using a 2-µm membrane filter. Degas for 1 hour with a vacuum and then add methanol (100 mL/L buffer). Stir the mixture for 10 minutes at 40 °C. Further degas the mixture for 10 minutes by slowly bubbling nitrogen gas through the mixture. Store tightly capped at room temperature. (Note: Changes in the composition of the mobile phase will be necessary as the HPLC column ages and as catecholamine retention times decrease. To maintain peak integrity and a consistent retention time, the concentration of methanol is decreased and that of the ion-pair reagent increased during the lifetime of the column [5 to 6 months]. With a new column, begin with the mobile phase containing 50 mg/L octyl sulfate and 10% methanol. Adjust the methanol concentration to sharpen peaks and to optimize retention times. Allow 1 to 2 hours between adjustments for the column to equilibrate with the mobile phase. Full equilibration requires 3 to 4 hours. Overnight equilibration may be more convenient.)
16. Bio-Rex 70 exchange resin (50 to 100 mesh, Bio-Rad Laboratories). Prepacked columns may be obtained from Bio-Rad. Alternatively, the resin may be washed and packed into plastic columns as follows:
    a. With gentle manual agitation, wash the resin with successive volumes of hydrochloric acid, 3 mol/L; NaOH, 3 mol/L; acetic acid, 3 mol/L; ammonium acetate, 1.0 mol/L (pH 6.5); and ammonium acetate, 0.1 mol/L (pH 6.5).
    b. Prepare a slurry of about 3 g resin and 15 mL ammonium acetate buffer, 0.1 mol/L (pH 6.5).
    c. Pipette the resin slurry into a plastic chromatography column, 1 cm I.D. × 8 cm in length.
    d. Allow the resin to pack in each column to a height of about 2.5 cm.
    e. Store packed columns at 4 °C after carefully sealing both tip and cap with parafilm. Stable for at least 1 year.
17. Nitrogen gas, prepurified, 99.995% minimum purity.

Instrumentation

A commercially available HPLC system equipped with a 25 × 0.4 cm (I.D.) reversed-phase C_{18} (average particle diameter, 5 or 10 mm) column and an electrochemical detector is suitable.

METHOD 29-4 Determination of Urinary Free Catecholamines by HPLC/EC—cont'd

Controls

Three urine controls are included in every run. For example, Bio-Rad Lyphochek Quantitative Urine Control, Levels 1 and 2 (Bio-Rad Clinical Diagnostics Group, Hercules, Calif.) are reconstituted each day and processed for immediate use. A 24-hour urine collection from a healthy individual is also used as a control pool. This urine is adjusted to pH 3 with hydrochloric acid, 6 mol/L, and spiked with the catecholamine stock calibrator, 10 mL per L of urine. Six-milliliter aliquots of the spiked urine are frozen in polypropylene vials and stored for future test runs.

Procedure

Sample Preparation

1. Into separate 50-mL centrifuge tubes, pipette 25.0 mL of each urine specimen and control.
2. Add 1.0 mL concentrated $HClO_4$. Cap and vortex mix for 15 seconds. Allow to stand for 10 minutes and then centrifuge for 5 minutes at 900 ×*g*.
3. Pipette 5.0 mL of each supernatant into 50-mL plastic beakers. Store the remaining volume of the supernatants in the freezer.
4. Transfer 5.0 mL of phosphate buffer, 10 mmol/L (pH 6.5), to a 50-mL beaker and add 50 µL of the catecholamine stock calibrator.
5. To all beakers, add 50 µL of the internal standard solution (3,4-dihydroxybenzylamine, 10 mg/L) and 15 mL of Na_2EDTA, 2.7 mmol/L. Adjust the pH to 6.5 ± 0.1 with NaOH, 0.5 mol/L, or H_3PO_4, 0.1 mol/L.

Ion-Exchange Chromatography

6. Prepare one Bio-Rex 70 ion-exchange column for each urine specimen, urine control, and calibrator to be analyzed. Insert the column into a suitable support rack and allow to drain into a drainage tray.
7. Quantitatively transfer the entire contents of each beaker onto separate columns, then rinse each beaker with 5 mL of water. Apply the rinse solutions to the respective columns and allow to drain completely.
8. Wash the columns with two 10-mL portions of water to remove urine contaminants.
9. When completely drained, add 7.0 mL H_3BO_3, 0.65 mol/L, to each column and collect the eluate in clean polypropylene vials, 17 × 100 mm.
10. Cap and mix the vials by inversion.
    Note: At this time, samples may be stored at 4 °C for up to 48 hours before injection into the HPLC system.

High-Performance Liquid Chromatography

11. Establish optimal operating conditions of the chromatographic and detection systems. Suggested conditions are as follows:
    Flow rate: 0.8 mL/min
    Potential: 720 mV
    Sensitivity: 100 nA/V
    Chart speed: 1 cm/min
12. Before the introduction of specimens onto the reversed-phase HPLC column, adjust the pH of each sample to 2.8 ± 0.1 with H_3PO_4. Inject 100 µL of each mixture. Figure A29-3 shows a representative chromatogram of catecholamines extracted from a urine calibrator.

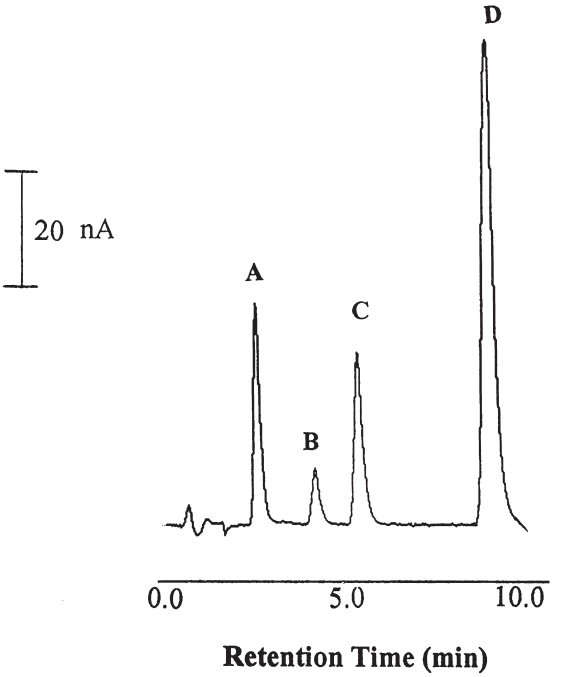

Figure A29-3 Representative chromatogram of catecholamines extracted from a urine calibrator. Norepinephrine **(A),** epinephrine **(B),** 3,4-dihydroxybenzylamine **(C),** and dopamine **(D)** retention are identified on the chromatogram.

Calculations

1. Identify catecholamine and internal standard peaks by relative retention times (in minutes). Measure peak heights (nA) directly from the chromatographic tracings.
   Example:

Calibrating Compound	Retention Time (min)	Peak Heights, ht (nA)
Norepinephrine	4.5	56
Epinephrine	5.5	14
Internal standard	6.4	18
Dopamine	9.0	108

2. Calculate ratio of peak heights (peak height of catecholamine/peak height of internal standard) for each urine specimen, urine control, and calibrator.
3. Calculate concentrations of unknown catecholamines:

$$CAT = R_u/R_c \times C_c \times 0.0104$$

where
CAT = unknown catecholamine concentration (µg/mL)
R_u = peak height ratio for unknown catecholamine
R_c = peak height ratio for corresponding catecholamine stock calibrator applied to ion-exchange resin
C_c = free-base concentration of catecholamine stock calibrator solution (mg/L = µg/mL)
Factor 0.0104 is derived as follows:
0.05/5.0 × 26.02/5.0 = 0.0104

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 29-4 Determination of Urinary Free Catecholamines by HPLC/EC—cont'd

where
0.05 = volume (mL) of catecholamine stock calibration applied to ion-exchange column
5.0 = volume (mL) of deproteinized urine applied to exchange column
25.0 = 24-hour urine aliquot (mL)
26.0 = total volume (mL) of deproteinized mixture (urine and perchloric acid)

4. Calculate 24-hour catecholamine excretion:

$$CAT/d = CAT \times TV$$

where
CAT, μg/d = catecholamine excretion per day
CAT, μg/mL = unknown catecholamine concentration
TV, mL = 24-hour urine volume

Comments

Amperometric detectors for catecholamine analysis by HPLC consist of carbon-paste or glassy-carbon working electrodes. Carbon paste consists of very finely divided particles of graphite and a binder that is mixed thoroughly to the consistency of a semidry paste. The binder holds the particles of graphite together as an integral unit and should be inert, both chemically and physically, to maintain sensitive electrode performance with minimal noise. Paraffin oil and silicone grease have proved most satisfactory and are popular in this regard. However, the choice of the binder depends on its solubility in the mobile phase; acetonitrile, a constituent of many mobile phases, dissolves paraffin oil; carbon paste using paraffin oil as binder would be obviously unsuitable under this condition. Glassy carbon has also come into use as a general-purpose electrode for amperometric detectors. Glassy carbon is a hard, brittle, solvent-impervious electrode material. Because it is 100% carbon, the chemical and physical resistance of glassy carbon to all mobile phases is unequaled. Detector characteristics, such as linearity and electron transfer property, are comparable for both electrodes. However, the carbon-paste electrode under optimal operating conditions provides more sensitive detection than that obtained using the glassy-carbon electrode.

METHOD 29-5 Determination of Urinary Free Catecholamines by LC-MS/MS

Submitted by Mark M. Kushnir, M.S. (ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, Utah) and Elizabeth L. Frank, Ph.D. (Department of Pathology, ARUP Laboratories, University of Utah School of Medicine, Salt Lake City, Utah)

Principle

An internal standard, phenylboronic acid (PBA) in a buffer solution, and extraction solvent are added to calibrators, controls, and patient samples. Samples are vortexed, centrifuged, and the organic phase is transferred to a new set of tubes. Acetic acid solution and 1-octanol are added to the tubes and catecholamines are extracted into aqueous solution. The organic phase is discarded, the aqueous solution is transferred into autosampler vials, and aliquots are injected onto the liquid chromatograph-tandem mass spectrometer (LC-MS/MS).

Advantages of the LC-MS/MS method for catecholamine (CATS) analysis compared with commonly used high performance liquid chromatography (HPLC) methods include significantly greater instrument throughput and improved specificity.

The specificity of this sample preparation method is based on the difference in affinity to PBA of CATS and potentially interfering compounds present in the sample matrix. CATS react with PBA in an alkaline solution that promotes the existence of the boronate ion, $Ph_2B(OH)^-$, a reactive form of PBA. Compounds containing vicinal *cis*-diol groups, such as those present in CATS, covalently bind to the boronate ion with the concomitant release of a molecule of water. The product PBA-catecholamine complex is polar and must be coupled with an ion-pairing reagent, such as tetraoctylammonium bromide, to be extracted into a nonpolar solvent. The complexation reaction requires a pH above 8.5, while release of CATS from the complex takes place in acidic solution.

Collision energies were selected to provide an optimal signal for each product ion. Voltages on the collision cell are alternated accordingly for each multiple reaction monitoring (MRM) transition specified in the acquisition scan. Alternating the collision cell voltages produces consistent product ion response ratios for qualitative confirmation of the catecholamines. The conditions employed produce satisfactory sensitivity and specificity for the selective detection of CATS in urine.

Specimen Collection and Storage

An aliquot (3.0 mL) from a random or 24-hour urine collection is required. The sample should be stored at refrigerator temperature during a timed collection and until testing is performed. The total 24-hour urine volume should be recorded (accurate to 5 mL). Alkaline specimens (pH > 7) and specimens stored at ambient temperature are not acceptable. Adjusting the pH to 2-3 by adding acid, such as 6 mol/L HCl, to the sample during collection can enhance stability of the catecholamines. Specimens are stable frozen for 6 months. The minimum sample volume is 1.0 mL.

Reagents

1. Acetic acid ($C_2H_4O_2$, 0.08 mol/L). Add 0.5 mL of glacial acetic acid to 50 mL of deionized water and mix. Bring the total volume to 100 mL with deionized water. Stable for 2 months at 20 °C.
2. Formic acid (CH_2O_2, 0.007 mol/L). To prepare 500 mL of this reagent, measure 500 mL of deionized water into a 1 L beaker. Stir and add 150 µL of formic acid. Mix for 15 minutes. Stable for 5 days at 20 °C.
3. 1-Octanol ($C_8H_{18}O$).
4. Stock calibrator diluent. Acetic acid (0.08 mol/L)/sodium metabisulfite ($Na_2S_2O_5$, 0.005 mol/L) solution. To prepare 100 mL of this reagent, volumetrically add 100 mL of 5 mL/L acetic acid to a 150-mL flask. Stir and add 100 mg of sodium metabisulfite. Mix until the solid is dissolved completely. Stable for 1 week at 20 °C.
5. Catecholamine stock calibrators. Epinephrine, norepinephrine, or dopamine (1.0 g/L) in acetic acid/sodium metabisulfite diluent (AASM). Stock solutions for each catecholamine are prepared in separate tubes. Using a 5 mL volumetric pipette, add exactly 5.0 mL of AASM diluent to a screw top test tube labeled with the name of the calibrator. Weigh 5.00 mg of epinephrine ($C_9H_{13}NO_3$), 9.43 mg of norepinephrine bitartrate salt ($C_8H_{11}NO_3 \cdot C_4H_6O_6$), or 6.19 mg of dopamine hydrochloride ($C_8H_{11}NO_2 \cdot HCl$). Transfer the solid into a labeled tube. Cap and mix using a rocker or vortex until the solid is dissolved completely. Stable for 1 year at −70 °C.
6. Catecholamine working calibrator. Epinephrine, norepinephrine, and dopamine (0.5 mg/L). In a 50-mL volumetric flask place 40 mL of methanol and 25 µL each of epinephrine, norepinephrine, and dopamine stock calibrator solutions. Add methanol to a total volume of 50 mL and mix. Stable for 6 months at −70 °C.
7. Catecholamine stock internal standard solutions. Epinephrine-d_3, norepinephrine-d_3, and dopamine-d_4 (1.0 g/L) in AASM. Stock solutions for each internal standard are prepared in separate tubes. Weigh 5.00 mg of epinephrine-d_3 ($C_9H_{10}D_3NO_3$), 9.36 mg of norepinephrine-d_3 bitartrate salt ($C_8H_8D_3NO_3 \cdot C_4H_6O_6$), or 6.16 mg dopamine-$d_4$ hydrochloride ($C_8H_7D_4NO_2 \cdot HCl$). Transfer the solid into the corresponding tube. Using a 5-mL volumetric pipette, add exactly 5.0 mL of AASM diluent to a screw top test tube labeled with the name of the deuterated catecholamine standard. Cap and mix using a rocker or vortex until the solid is dissolved completely. Stable for 2 years at −70 °C.
8. Catecholamine working internal standard. Epinephrine-d_3 and norepinephrine-d_3 (1.5 mg/L) and dopamine-d_4 (3.0 mg/L). In a 50-mL volumetric flask, place 40 mL of methanol and 75 µL of each epinephrine-d_3 and norepinephrine-d_3 stock internal standard solutions and 150 µL of dopamine-d_4 stock internal standard solution. Add methanol to a total volume of 50 mL and mix. Stable for 1 year at −70 °C.
9. Catecholamine-free urine. Catecholamine-free urine is prepared by incubation of a nonpathological urine sample at alkaline pH. Adjust 300 mL of urine to pH > 13 using sodium hydroxide (NaOH, 2 mol/L). Incubate the urine at 40 °C to 45 °C for 48 hours. Analyze an aliquot of the urine using this procedure. If the concentrations of catecholamines in the urine are above the limit of detection of the method, incubate the sample for an additional 24 hours. If the catecholamine concentrations are less than or equal to the limit of detection, dilute urine with water to 600 mL. Adjust the pH to between 3 and 4 with hydrochloric acid (HCl, 6 mol/L). Stable for 6 months at −70 °C.
10. Diphenylboric acid 2-aminoethyl ester ($C_{14}H_{16}BNO$, PBA) solution. In a 1 L beaker dissolve 106 g of ammonium chloride (NH_4Cl) and 5 g of ethylenediaminetetraacetic acid ($C_{10}H_{16}N_2O_8$, EDTA) in 900 mL of water. Adjust the pH of the solution to 8.95 ± 0.05 with ammonium hydroxide (NH_4OH).

METHOD 29-5 Determination of Urinary Free Catecholamines by LC/MS/MS—cont'd

Dissolve 0.5 g of PBA in this solution and add deionized water to a total volume of 1000 mL. Mix until PBA is completely dissolved. Stable for 3 months at 4 °C.

11. Tetraoctylammonium bromide ($C_{32}H_{68}NBr$, TOAB) solution. TOAB (11 mmol/L) in heptane (C_7H_{16}). Into a 1 L beaker add 10 mL of 1-octanol and 6 g of TOAB. Add heptane to a total volume of 1000 mL. Mix until completely dissolved. Stable for 3 months at 4 °C.
12. Mobile phase. Tetrahydrofuran (THF, C_4H_8O)/formic acid (0.007 mol/L), (60 : 40). To prepare 500 mL of mobile phase, pour 300 mL of THF into a 1 L beaker. Add 200 mL of 0.07 mol/L aqueous formic acid. Mix. Stable for 3 days at 20 °C.
13. Needle wash solution. Methanol (CH_4O)/2-propanol (C_3H_8O)/water, (60 : 20 : 20). To prepare 1000 mL of needle wash solution, pour 600 mL of methanol into a 1000 mL flask. Add 200 mL of 2-propanol and then add 200 mL of deionized water. Mix. Stable for 5 days at 20 °C.

Instrumentation

A commercially available HPLC instrument equipped with a column (Allure Basix, 50 mm × 2 mm, 5 µm particles; Restek Corp., Bellefonte, Pa.); a tandem mass spectrometer with ion spray interface.

Quality Control

Two commercial urine controls (Bio-Rad Laboratories, Irvine, Calif.) are included in every run. Catecholamine-free urine serves as a negative control.

Procedure

Sample Preparation

1. Label a 2-mL microcentrifuge tube for each calibrator, control, and urine specimen.
2. Prepare an unextracted calibrator by aliquoting 6 µL of working calibrator in an empty tube. Add 50 µL of 10 mL/L acetic acid to this tube. This sample is not extracted.
3. Quantitatively add into empty tubes 30 µL of the working internal standard solution.
4. Prepare a calibration curve at concentrations of 10, 25, 100, and 200 µg/L. Add 300 µL of catecholamine-free urine in each tube. Aliquot to the labeled microcentrifuge tubes 6, 15, 60, and 120 µL of working calibrator solution.
5. Aliquot 300 µL of each urine sample in labeled microcentrifuge tubes.
6. Add 900 µL of TOAB extraction solvent to each tube.
7. Add 750 µL of PBA/buffer solution to each tube.
8. Vortex tubes on high speed for 3 minutes; centrifuge at 15,000 ×*g* for 3 minutes.
9. Label a clean tube for each calibrator, control, and urine specimen. Add 50 µL of 0.08 mol/L acetic acid and 500 µL of 1-octanol to each tube.
10. Transfer 700 µL of the organic layer from each sample to the appropriately labeled tube.
11. Vortex samples on high speed for 3 minutes; centrifuge at 15,000 × *g* for 3 minutes.
12. Using vacuum aspiration, remove the upper, organic layer from each sample tube.
13. Transfer the aqueous solution from each sample to labeled autosampler vials.

High Performance Liquid Chromatography-Tandem Mass Spectrometry

Inject the unextracted calibrator, extracted calibrators, controls, and samples.

Suggested operating conditions:

Flow rate	0.4 mL/min
LC column effluent split flow	60-80%
Column temperature	Ambient
Injection volume	3-5 µL
Number of syringe washes	Preinjection: 5
	Postinjection: 5

The mass spectrometer is tuned for unit resolution of Q_1 and Q_3. Voltages are optimized for maximum sensitivity.

MRM transitions monitored (m/z):

Epinephrine	184 to 107, 184 to 77
Epinephrine-d_3	187 to 110
Norepinephrine	170 to 107, 170 to 77
Norepinephrine-d_3	173 to 110
Dopamine	154 to 91, 154 to 65
Dopamine-d_4	158 to 95

Transitions m/z 184 to 107, 170 to 107, and 154 to 91 are quantitative, and transitions m/z 184 to 77, 170 to 77, and 154 to 65 are qualitative.

Results

1. Evaluate the chromatography of the unextracted calibrator, calibrators, and controls for acceptable peak shapes and area counts.
2. The coefficient of determination (R^2) for the calibration curve should be greater than 0.990.
3. The catecholamine concentration of the negative control should be less than the limit of detection for each analyte.
4. Qualitative ion mass ratios of (m/z 184 to 77)/(m/z 184 to 107) for epinephrine, (m/z 170 to 77)/(m/z 170 to 107) for norepinephrine, and (m/z 154 to 65)/(m/z 154 to 91) for dopamine must be within the range established by the calibration. This is typically ±50% of the average of the ion-mass ratios observed in the calibrators of the run.
5. Evaluate the results for acceptable chromatography, ion ratios, and area counts as compared with the calibrators.

Calculations

Calculations are performed using peak area ratios relative to the corresponding internal standard. Commercial data analysis software is used.

Sample chromatograms for each analyte are shown in Figure A29-4.

Notes

Acidic specimens (pH < 2) may not give adequate results. The pH of such a sample can be adjusted and the sample can be reextracted and reanalyzed.

Interferences

Compounds evaluated for interference using this method: acetaminophen, caffeine, cimetidine, dexamethasone, diazepam, isoetharine, isoproterenol, labetalol, levodopa, metoclopramide, metanephrine, 3-methoxytyramine, methyldopa, normetanephrine,

METHOD 29-6 Determination of Urinary Metanephrine and Normetanephrine by HPLC/EC

Submitted by Thomas G. Rosano, Ph.D.
Department of Pathology and Laboratory Medicine, Albany Medical College and Hospital, Albany, N.Y.

Principle

An aliquot of urine is combined with an internal standard (4-O-methyldopamine), and the mixture is hydrolyzed with acid to convert all the metanephrines to their free unconjugated forms. Isolation of metanephrines from the sample matrix is accomplished using two disposable minicolumns. The hydrolyzed urines, diluted with an ammonium pentaborate buffer, are first applied to a weak acid cation-exchange resin. The adsorbed metanephrines are then eluted with ammonium hydroxide directly onto a strong quaternary amine anion-exchange column, which separates the metanephrines from nonphenolic amines and more hydrophobic phenolic compounds. The final elution uses a weak ammonium acetate buffer; the eluate is then injected onto a reversed-phase HPLC system. Electrochemical detection is used to quantify metanephrine and normetanephrine separately.

Specimen Collection and Storage

A complete 24-hour urine specimen is collected in a clean container containing acid as a stabilizing preservative (e.g., 10 mL of HCl, 6 mol/L). The specimen should be refrigerated during collection. Overnight or untimed (random) urine collections should be acidified to a pH between 1 and 3 immediately after collection. The total urine volume is measured and recorded after collection, and a 50-mL aliquot is reserved for analysis. Samples are refrigerated until the test is performed or are stored frozen indefinitely.

Reagents

1. Combination normetanephrine and metanephrine calibrator (Bio-Rad Laboratories, Catalog No. 195-6021). Reconstitute the lyophilized urine calibrator with 25 mL of HCl, 0.05 mol/L. Let stand 10 minutes, then agitate gently to dissolve. Reconstituted calibrator is stable 30 days at 2 °C to 8 °C.
2. Internal standard, 4-O-methyldopamine (Bio-Rad Laboratories, Catalog No. 195-6022). Reconstitute lyophilized calibrator with 25 mL of HCl, 0.05 mol/L. Agitate gently to dissolve. Stable for 3 months at 2 °C to 8 °C.
3. HPLC column test solution for metanephrines (Bio-Rad Laboratories, Catalog No. 195-6024). Store refrigerated. Dilute 20 μL in 8 mL of mobile phase before each use.
4. Cation resin columns filled with weakly acidic cation-exchange resin (Bio-Rad Laboratories, Catalog No. 195-6017). Store at 2 °C to 8 °C.
5. Anion resin columns filled with strongly basic anion-exchange resin (Bio-Rad Laboratories, Catalog No. 195-6018). Stable at room temperature.
6. NaOH, 0.5 mol/L. Dissolve 2.0 g NaOH in 80 mL of distilled water. Dilute to 100 mL with water and mix. Stable at room temperature.
7. Hydrochloric acid, 2 mol/L. Under a fume hood, slowly add 50 mL of concentrated hydrochloric acid to 250 mL of distilled water with continuous mixing. Continue stirring for 5 minutes or until the solution cools to room temperature. Stable at room temperature.
8. Hydrochloric acid, 0.05 mol/L. Dilute 1.0 mL concentrated hydrochloric acid to 250 mL with distilled water and mix. Stable at room temperature.
9. Ammonium pentaborate buffer. Dissolve 40 g ammonium pentaborate and 1.0 g Na_2EDTA in 900 mL distilled water. Dilute to 1 L. Mix well and transfer to a 1000-mL dispenser set to deliver 4.0 mL. Stable at room temperature up to 3 months.
10. NH_4OH, 2 mol/L. Under a fume hood, add 135 mL of concentrated NH_4OH to 865 mL distilled water. Mix well and transfer to a 1000-mL dispenser bottle set to deliver 8.0 mL. Stable at room temperature up to 3 months.
11. Acetic acid, 1 mol/L. Mix 5.7 mL of glacial acetic acid with 94.3 mL of distilled water. Stable at room temperature.
12. Elution buffer. Dissolve 15.4 g of ammonium acetate in 950 mL distilled water. Adjust the pH to 6.00 ± 0.05 using 1 mol/L of acetic acid. Dilute to 1 L with water and transfer to a 1000-mL dispenser set to deliver 5.0 mL. Stable at 2 °C to 8 °C for 3 months.
13. Monochloroacetic acid ($ClCH_2COOH$) mobile-phase solution. Dissolve 9.4 g of $ClCH_2COOH$, 3.3 g of NaOH, 1.0 g of Na_2EDTA, and 0.3 g of sodium octyl sulfate in 1 L of water. Adjust the pH to 3.0 to 3.1 with $ClCH_2COOH$. Add 75 mL of acetonitrile (CH_3CN). Store at room temperature for 3 months.
14. Citric acid mobile-phase solution. Dissolve 250 mg of NaOH, 18.61 mg of Na_2EDTA, 21.0 g of citric acid monohydrate, and 0.9 mL of diethylamine in 500 mL of water. Add 90 mL of acetonitrile. Dilute to 1 L with deionized water and adjust the pH to 2.55 with solid NaOH pellets.

METHOD 29-6 Determination of Urinary Metanephrine and Normetanephrine by HPLC/EC—cont'd

15. Working mobile-phase solution. Mix equal volumes of the 0.1 mol/L monochloroacetic acid and the 0.1 mol/L citric acid solutions. Filter and degas before use. The combined mobile phase is stable for 3 months at room temperature.

Instrumentation

A commercially available HPLC system equipped with a 3-µm phase II reversed-phase ODS (C_{18}) cartridge column, 3.2 mm I.D. × 10 cm (Bioanalytical Systems, Catalog No. MF 6213), and an amperometric detector are suitable.

Quality Control

Two urine controls are included in every run. Bio-Rad normal and abnormal urine controls are reconstituted each day with HCl, 0.05 mol/L, and processed for immediate use (Bio-Rad Laboratories, Catalog Nos. C-390-25 and C-395-25).

Procedure

Hydrolysis

1. Set the pH meter calibration at 7.00 using pH 7 buffer. Adjust the pH meter slope calibration to 1.00 using pH 1 buffer.
2. Pipette 2.0 mL of calibrator, controls, and patient samples into labeled 16 × 150-mm test tubes. Add 2.0 mL distilled water and 200 µL internal standard solution to each tube. Mix each tube briefly in a vortex mixer.
3. Add HCl (2 mol/L), drop by drop, to each tube until obtaining a pH between 0.8 and 1.0. Rinse the pH electrode with distilled water after measuring each sample. Recheck the pH 1 buffer every two to three samples.
4. To minimize evaporative losses, cover the tubes loosely with Parafilm.
5. Place the tubes in a boiling water bath under a hood for 30 minutes to allow complete hydrolysis of metanephrines.
6. Remove tubes from the water bath and allow them to cool to room temperature.

Ion-Exchange Chromatography

7. Label and prepare one cation-exchange column and one anion-exchange column for each calibrator, control, and sample. Prepare the columns, about five or six at a time, by shaking them up and down until completely suspending the resin. Allow the resin to settle. Remove the caps and then snap off the tips. Allow the columns to drain into the waste reservoir.
8. Recheck the pH 7 buffer and adjust pH meter calibration if necessary. Adjust slope to 4.00 using the pH 4 buffer.
9. To each tube, add 5.0 mL ammonium pentaborate buffer and 300 µL NaOH (0.5 mol/L). Mix in a vortex mixer. Check that the pH is between 6.0 and 7.0. If necessary, adjust pH with 100-µL aliquots of NaOH (0.5 mol/L) or acetic acid (1.0 mol/L).
10. Pour each sample into the cation-exchange column assigned to it and allow to drain completely.
11. Add 10 mL of distilled water to each column and allow to drain completely.
12. Place a polycolumn support over each anion-exchange column. Move the appropriate cation-exchange column over the anion-exchange column and insert it through the polycolumn support so that it is held in place.
13. Pipette 8.0 mL of NaOH (2 mol/L) into each upper cation-exchange column and allow it to drain completely through both columns. Remove and discard the cation-exchange columns.
14. Rinse each anion-exchange column with 5 mL of distilled water.
15. Replace the waste reservoir with a tube rack containing 16 × 150-mm test tubes. Make sure that the columns are located above marked tubes so that no sample will be spilled.
16. Dispense 5.0 mL of elution buffer into each column. Allow the columns to drain completely and then discard them.
17. Add 400 µL acetic acid (1 mol/L) to each tube and then mix them in a vortex mixer. If necessary, the eluates may be covered with Parafilm and stored overnight at room temperature. Eluates may also be stored for 1 week at 4 °C.

High-Performance Liquid Chromatography

18. Establish the optimal operating condition of the chromatographic and detection systems. Suggested conditions are:

Flow rate:	1.0 mL/min
Potential:	800 mV
Sensitivity:	20 or 50 nA/V
Chart speed:	1 cm/min

19. Inject 10 µL of the test mix into the HPLC system to check chromatographic retention times and detector sensitivity.
20. Inject 20 µL of each extract into the HPLC system. Figure A29-5 shows a representative chromatogram of metanephrines extracted from human urine.

Calculations

1. Identify metanephrine, normetanephrine, and internal standard peaks by comparing retention times of unknown peaks with retention times of known peaks in the test mix. Measure peak heights to nearest 0.5 mm. Verify that the internal standard peak

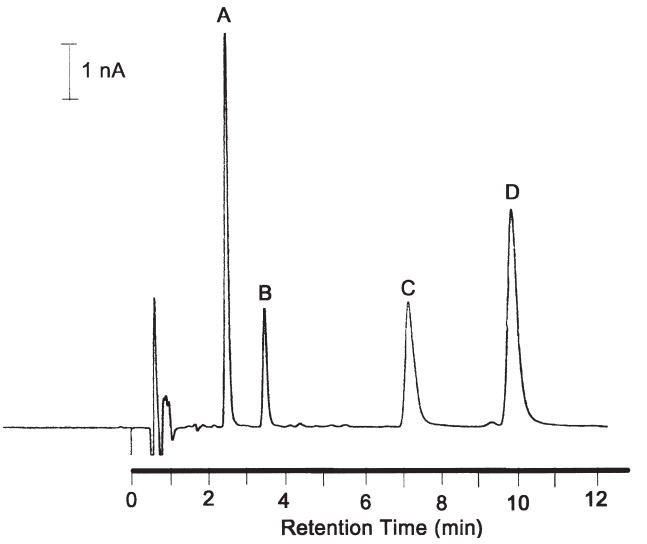

Figure A29-5 Representative chromatogram of metanephrines extracted from human urine. Normetanephrine **(A),** metanephrine **(B),** 3-methoxytyramine **(C),** and 4-O-methyldopamine **(D)** retention are identified on chromatogram.

METHOD 29-6 Determination of Urinary Metanephrine and Normetanephrine by HPLC/EC—cont'd

height for each unknown is at least 75% of the internal standard peak height for the calibrators.

2. Calculate the ratio of peak heights (peak height of unknown/peak height of internal standard) for each urine sample, urine control, and calibrator.
3. Calculate metanephrine and normetanephrine concentrations for controls and unknowns:

$$MN \text{ or } NMN = R_u/R_c \times C_c$$

where
MN = unknown concentration of metanephrine (μg/L)
NMN = unknown concentration of normetanephrine (μg/L)
R_u = peak height ratio of unknown
R_c = peak height ratio of corresponding calibrator
C_c = concentration of corresponding calibrator (μg/L)

4. Calculate 24-hour excretion:
MN or NMN (μg/d) = MN or NMN (μg/L) × 24-hour urine volume (L)
5. Calculate 24-hour excretion rate:
MN or NMN (μg/g creatinine) = MN or NMN (μg/L)/Urine creatinine concentration (g/L)

Reference

Adapted from Parker NC, Levtzow CB, Wright PW, Woodard LL, Chapman JF. Uniform chromatographic conditions for quantifying urinary catecholamines, metanephrines, vanillylmandelic acid, 5-hydroxyindoleacetic acid, by liquid chromatography, with electrochemical detection. Clin Chem 1986;32:1473-6.

METHOD 29-7 Determination of Urinary Metanephrine and Normetanephrine by LC-MS/MS

Submitted by Ravinder J. Singh, Ph.D.
Department of Laboratory Medicine and Pathology, Mayo Clinic and Foundation, Rochester Minn.

Principle

Urine samples are acidified and hydrolyzed for 20 minutes in a boiling water bath. Metanephrine and normetanephrine are extracted from the specimens using Waters HLB Oasis cartridges. The metanephrine and normetanephrine are eluted from the cartridges using 20% methanol and analyzed by LC-MS/MS using multiple reaction monitoring. Deuterated metanephrine (d_3-metanephrine) and deuterated normetanephrine (d_3-normetanephrine) are added before hydrolysis as internal standards. The following ion pairs are used for analysis:

Metanephrine:	180/148
Normetanephrine:	166/134
d_3-metanephrine:	183/151
d_3-normetanephrine:	169/137

A calibration curve, generated from 20% methanol spiked calibrators, is included with each batch of patient samples.

Specimen Collection and Handling

Requires 10 mL of urine (pediatric: 5 mL) from a 24-hour collection. Add 10 g (pediatric 3 g) of boric acid or 25 mL (pediatric 15 mL) of 50% acetic acid as a preservative at the start of the collection. Measure and record the volume of the 24-hour collection. Send specimen refrigerated in a plastic, 13-mL urine tube.

METHOD 29-7 Determination of Urinary Metanephrine and Normetanephrine by LC-MS/MS—cont'd

Urine Preservative Collection Options

Important Note: The addition of preservative or application of temperature controls must occur within 4 hours of completion of the collection *or* an acceptable preservative must be added at the *start* of the collection. Urine specimens that require that the preservative be added at the *start* of the collection are noted by an *(asterisk).

Ambient:	No
Refrigerated:	Yes*
Frozen:	Yes*
6 mol/L HCl	Yes*
Acetic Acid 50%:	Preferred*
Na_2CO_3:	Yes*
Toluene:	Yes*
HNO_3:	Yes*
Boric Acid:	Preferred*
Thymol:	Yes*

Reagents

1. Methanol, HPLC grade.
2. Chromatographic mobile phase. Dissolve 3.1 g ammonium acetate in 850 mL of RO H_2O (water produced by reverse-osmosis) and add 150 mL of methanol. Degas the solvent by placing on a magnetic stir plate, stirring under vacuum. Degas for 3 to 5 minutes or until bubble formation is slight. Store at room temperature. Expiration—1 week.
3. Rinse solution. Combine 1500 mL of methanol and 500 mL of RO H_2O. Degas as described for chromatographic mobile phase. Store at room temperature. Expiration—1 week.
4. 20% Methanol-Cartridge elution solvent. Combine 800 mL of methanol and 3200 mL RO H_2O; mix. Store at room temperature. Expiration—1 month.
5. 70% Methanol-Cartridge wash solvent. Combine 2800 mL of methanol and 1200 mL RO H_2O; mix. Store at room temperature. Expiration date—1 month.
6. DL-Metanephrine hydrochloride. Sigma, catalog No. M-8625. Store as indicated on package label.
7. DL-Normetanephrine hydrochloride. Sigma, catalog No. N-7127. Store as indicated on package label.
8. Metanephrine/normetanephrine stock calibrator 1.0 mg/mL. Dissolve 11.845 mg DL-metanephrine hydrochloride and 11.992 mg DL-normetanephrine hydrochloride in 10 mL of 0.05 mol/L HCl to give a stock calibrator of 1 mg/mL metanephrine/normetanephrine. Store the stock calibrator in 1.0-mL aliquots at −70 °C. Expiration—No expiration. Store the aliquots in use at 4 °C. Expiration—3 months.
9. d_3-Metanephrine/d_3-Normetanephrine stock internal standard. Dissolve 10 mg of deuterated metanephrine and 20 mg deuterated normetanephrine in 10 mL of 0.05 mol/L HCl to give a 1 mg/mL d_3-metanephrine-2 mg/mL d_3-normetanephrine stock internal standard.

   Store the stock internal standard in 1.0-mL aliquots at −70 °C. Expiration—No expiration.
10. Store the aliquot in use at 4 °C. Expiration—3 months
11. Working internal standard. Add 200 µL of the d_3-metanephrine/d_3-normetanephrine stock internal standard to 19.8 mL of 20% methanol. Store at 4 °C. Expiration—2 weeks.
12. 4.5 mol/L HCl. Add 187.5 mL of concentrated HCl (EM Science, Catalog No. 7647-01-1) to RO H_2O and dilute to 500 mL. Store at room temperature. Expiration—6 months.
13. 5.0 mol/L NaOH. Dissolve 200 g of sodium hydroxide pellets (Fisher Scientific, Catalog No. S318-500) in RO H_2O, cool and dilute to 1 L. Store at room temperature. Expiration—6 months.
14. 2.0 mol/L Phosphate Buffer. Dissolve 284 g of Na_2HPO_4 (Fisher Scientific, Catalog No. S374-500) and 272 g KH_2PO_4 (Fisher Catalog No. P285-500) in RO H_2O and dilute to 2000 mL.

Consumables

1. Autosampler Vials: 0.2 mL, 8 mm vials (Kimble Glass Inc.) from Fisher: Catalog No. 0334064 200/pk.
2. Caps: 8 mm snap-it cap (National Scientific Co.) from Fisher: Catalog No. 0337749 100/pk or 1000/case.
3. Extraction Cartridges: Oasis HLB 1cc (30 mg) Extraction Cartridges from Waters: Catalog No. WATO94225.

Instrumentation

1. A PE Sciex API 2000 Tandem mass spectrometer is used to monitor multiple ion pairs.
2. A Perkin Elmer HPLC system is used for sample separation and introduction into the mass spectrometer.
3. A computer with the Analyst Software from PE Sciex is used for data processing.
4. The analytical column is a Supelco Discovery RP Amide C16 HPLC column. 5.0 cm × 4.6 mm, 5 µm. Catalog No. 505005.
5. The guard column is Supelco Discovery RP-AmideC16 Guard Column. 2 cm × 2.1 mm, 5 µm. Catalog No. 505110.
6. The guard column holder is a Supelco Direct Connect Holder for 4.6 mm ID column. Catalog No. 55205.
7. Visiprep Solid Phase Extraction (SPE) Vacuum Manifold from Supelco: Catalog No. 57250-U.

Calibration

1. 20 µg/mL metanephrine/normetanephrine stock calibrator. Add 20 µL of the metanephrine/normetanephrine stock calibrator to 980 µL of 20% methanol, mix and cap.
2. 2 µg/mL metanephrine/normetanephrine stock calibrator. Dilute 100 µL of the 20 µg/mL metanephrine/normetanephrine stock calibrator with 0.9 mL of 20% methanol.
3. 0.2 µg/mL metanephrine/normetanephrine stock calibrator. Dilute 100 µL of the 2 µg/mL metanephrine/normetanephrine stock calibrator with 0.9 mL of 20% methanol.
4. Prepare working calibrators according to the following table:

Quality Control/Quality Assurance

Donor urine collections are used for controls (abnormal control may need to be spiked to reach appropriate level). They are stored as 20-mL aliquots at –20 °C for up to 2 years. Three urine controls are included in each assay.

Procedure

1. Centrifuge a 2.0-mL portion of each 24-hour and random urine collection sample and sample control in appropriately labeled 12- × 75-mm glass tubes to remove all sediment and particulate matter.
2. Transfer 1.0 mL of each urine sample and control to appropriately labeled 16- × 125-mm glass tubes.
3. Add 50 µL of 4.5 mol/L HCl to each tube.
4. Add 25 µL of working internal standard to each tube and vortex.
5. Hydrolyze each tube for 20 minutes in a boiling water bath.
6. Remove the tubes from the water bath and allow samples to cool for 5 minutes at room temperature.
7. Add 50 µL of 5.0 mol/L NaOH to each tube and vortex.
8. Add 500 µL of 2 mol/L phosphate buffer. Check pH of each sample. The pH should be 7.0 (±1.0). If pH is outside this range, add 4.5 mol/L HCl or 5.0 mol/L NaOH drops until pH is acceptable.
9. Prepare a Waters HBL Oasis cartridge for each control and sample as follows using the Visiprep SPE vacuum manifold described in the equipment section of this procedure.
   - Add 1.0 mL of methanol and pull through the cartridge using a vacuum. Do not allow the cartridge to become dry (do not pull air through the cartridge for longer than 30 seconds). For slow flowing cartridges, push the methanol through manually.
   - Add 1.0 mL of RO H_2O and pull through the cartridge using a vacuum. Do not allow the cartridge to become dry (do not pull air through the cartridge for longer than 30 seconds). For slow flowing cartridges, push the RO H_2O through manually.
10. Apply each control and sample to the appropriate cartridge. Apply slight vacuum, keeping the flow rate of the sample through the cartridge *less* than 2 mL/min.
11. Wash each cartridge with 1.0 mL of RO H_2O. Apply slight vacuum, keeping the flow rate of the RO H_2O through the cartridge *less* than 2 mL/min.
12. Place collection tubes in the extraction manifold. Add 1.0 mL of 20% methanol to each cartridge. Apply slight vacuum, keeping the flow rate of the 20% methanol through the cartridge *less* than 2.0 mL/min, collecting the eluate in the collection tubes.
13. Transfer the eluate of each control and sample to an appropriately labeled autosampler vial and apply cap.
14. To reuse the cartridges: wash each cartridge with 1 mL of 20% methanol, 2 mL of 70% methanol, and 2 mL of methanol. Cartridges may be used 5 times.
15. Prepare the calibration curve as described in Calibration.
16. Initiate analysis and quantitation of the assay on the PE Sciex 2000 Tandem Mass Spectrometer using Analyst software.

Calculations

For 24-hour samples:
Metanephrine and normetanephrine concentration µg/24hr:
Tandem MS value ng/mL × TV/1000 = µg/24hr
(TV = the total volume of urine in mL for the 24-hour period)
For random samples:
Report the answer as µg metanephrine/g creatinine:
Tandem MS value ng/mL ÷ (creatinine value mg/dL ÷ 100) = µg/g

Procedural Notes

1. Precision

a. Intraassay, n = 20

Metanephrine			
Mean	61 ng/mL	717 ng/mL	3038 ng/mL
CV	7.8%	3.9%	4.8%

METHOD 29-7 Determination of Urinary Metanephrine and Normetanephrine by LC-MS/MS—cont'd

2. Recovery
   a. Metanephrine. Four samples were spiked with 144, 575, and 2300 ng/mL of metanephrine and assayed. Recovery range was 92% to 109% with a total average of 101%. Below are two samples from the recovery study.

Spike (ng/mL)	Measured Metanephrine ng/mL	% Recovery
0	53	
144	205	106%
575	677	109%
2300	2380	101%
0	54	
144	203	103%
575	644	103%
2300	2310	98%

   b. Normetanephrine. Four samples were spiked with 144, 575, and 2300 ng/mL of normetanephrine and assayed. Recovery range was 92% to 113% with a total average of 102%. Below are two samples from the recovery study.

Spike (ng/mL)	Measured Normetanephrine ng/mL	% Recovery
0	89	
144	233	100%
575	651	98%
2300	2530	106%
0	114	
144	266	106%
575	733	107%
2300	2730	113%

3. Linearity.
   a. Metanephrine. Four samples were run straight, ×2, ×5, ×20, ×40 (diluted in RO H_2O) and assayed. The expected range was 88% to 109% with a total average of 103%. Below are two samples from the linearity study.

Dilution	Measured Metanephrine ng/mL	Expected Metanephrine ng/mL	% Expected
Straight	3080		
×5	629	616	102%
×10	272	308	88%
×20	163	154	106%
×40	78	77	101%
Straight	130		
×2	72	65	111%
×5	27	26	105%
×10	14	13	105%
×20	7.1	6.5	109%

   b. Normetanephrine. Four samples were run straight, ×2, ×5, ×20, ×40 (diluted in RO H_2O) and assayed. The expected range was 95% to 113%, with a total average of 101%. Below are two samples from the linearity study.

Calibration Curves for Analysis of Metanephrine and Normetanephrine.

1. Correlation with photometric total metanephrines. 100 samples were assayed on the photometric method, X (with normal spectral curves), and LC-MS/MS method, Y, and analyzed by linear regression.

$$Y = 0.815\,X - 0.0065; \quad r = 0.82$$

2. Sample stability.
   a. Ambient. Stability was determined on unpreserved, acetic acid, and boric acid specimens. The following table outlines results at 7 days.

Specimen Type	Metanephrine % difference Range	Metaphrine Average % Difference	Normetaphrine % Difference Range	Normetaphrine Average % Difference
Unpreserved	−1.7% to 20.5%	4.7%	−17.8% to 28.1%	8.9%
Acetic acid	−11.9% to 13.3%	5.7%	−3.4% to 16.4%	11.0%
Boric acid	−4.4% to 4.9%	0.5%	3.3% to 16.5%	11.3%

   b. Refrigerated. Stability was determined on unpreserved, acetic acid, and boric acid specimens. The following table outlines results at 7 days.

Specimen Type	Metanephrine % Difference Range	Metaphrine Average % Difference	Normetaphrine % Difference Range	Normetaphrine Average % Difference
Unpreserved	−10.3% to 14.7%	0.4%	−17.1% to 13.1%	0.2%
Acetic acid	−9.5% to 10.0%	2.6%	−3.6% to 17.1%	9.3%
Boric acid	−6.5% to 31.7%	9.6%	−10.5% to 19.5%	3.1%

   a. Freeze-Thaw. Freeze-thaw was determined on acetic acid and boric acid specimens. The following table outlines results after three freeze-thaw cycles.

Specimen Type	Metanephrine % Difference Range	Metaphrine Average % Difference	Normetaphrine % Difference Range	Normetaphrine Average % Difference
Acetic acid	−26.5% to 4.8%	−9.4%	−13.7% to 3.5%	−4.7%
Boric acid	−20.3% to 5.1%	−9.2%	−21.4% to −2.7%	−12.6%

METHOD 29-8 Determination of Urinary Vanillylmandelic Acid by HPLC/EC

Submitted by Thomas G. Rosano, Ph.D.
Department of Pathology and Laboratory Medicine, Albany Medical College and Hospital, Albany, N.Y.

Principle

An aliquot of urine is mixed with an internal standard (isovanillylmandelic acid, iso-VMA) and then applied to a strongly basic anion-exchange resin that has been preconditioned with an acetate buffer. Uric acid and hydrophobic acids, such as HVA, are removed from the cleanup column during an acetic acid–ethanol wash step. VMA and iso-VMA are eluted with H_3PO_4 and subsequently resolved by reversed-phase HPLC under optimized isocratic conditions. The VMA concentration is determined electrochemically using an amperometric detection system.

Specimen Collection and Storage

A complete 24-hour urine collection is recommended because variations in VMA excretion occur throughout the day. Shorter collection times may be useful provided that VMA results are expressed per milligram of creatinine. The urine should be collected in a clean container that contains acid as a stabilizing preservative (e.g., 10 mL of HCl, 6 mol/L, for a 24-hour collection). The specimen should be refrigerated during collection. The total urine volume is measured and recorded; a 50-mL aliquot is stored at 4 °C until the test is performed or may be frozen and stored indefinitely. No dietary restrictions during urine collection are necessary.

Reagents

1. Resin column filled with strongly basic anion-exchange resin (Bio-Rad Laboratories, Catalog No. 195-5005).
2. Sodium acetate, 2 mol/L. Dissolve 82 g of sodium acetate in distilled water to a final volume of 0.5 L. This solution is stable for 1 month at 4 °C.
3. Acetic acid, 2 mol/L. Dilute 57.5 mL glacial acetic acid in distilled water to a final volume of 0.5 L.
4. KH_2PO_4, 1 mol/L. Dissolve 68.05 g KH_2PO_4 in distilled water to a final volume of 0.5 L. This solution is stable for 1 month at 4 °C.
5. NaOH, 0.5 mol/L. Dissolve 2.0 g NaOH in distilled water and dilute to 0.1 L. Store tightly capped.
6. HCl, 0.05 mol/L. Dilute 1.0 mL of concentrated HCl in distilled water to a final volume of 0.25 L.
7. Acetate buffer, 0.08 mol/L, pH 6.1. Mix 40 mL of sodium acetate, 2 mol/L, with 1.2 mL of acetic acid, 2 mol/L. Dilute to 1 L. Adjust the pH to 6.10 ± 0.05 with acetic acid, 2 mol/L, or NaOH, 0.5 mol/L. This solution is stable for 1 month at 4 °C.
8. Wash reagent, acetic acid–ethanol. Mix 250 mL acetic acid, 2 mol/L, and 250 mL ethanol, 95%. This solution is stable for 1 month at 4 °C.
9. Elution reagent, H_3PO_4. Dilute 250 mL of H_3PO_4 (2 mol/L) in distilled water to a final volume of 1 L.
10. VMA calibration solutions.
    a. Stock calibrator of VMA, 1 mg/mL. Accurately weigh 10 mg of VMA (Sigma Chemical Co., Catalog No. H0131) and dissolve in 10 mL of HCl, 0.05 mol/L, in a volumetric flask. Store at 4 °C. This solution is stable for 6 months under refrigeration.
    b. Working calibrators, 5, 10, and 20 mg/L. Dilute 50, 100, and 200 µL of the stock calibrator to 10 mL with HCl, 0.05 mol/L. Prepare fresh before use.
11. Internal standard, iso-VMA, 1 mg/mL. Dissolve 10 mg of DL-3-hydroxy-4-methoxymandelic acid (Sigma Chemical Co., Catalog No. H3139) in 10 mL of HCl, 0.05 mol/L. Store at 4 °C. This solution is stable for 6 months at 4 °C.
12. Mobile phase, ethanol/phosphate buffer. Mix 40 mL KH_2PO_4 (1 mol/L) with 5 mL of phosphoric acid, 2 mol/L. Dilute to 1 L with distilled water. Adjust the pH to 3.02 ± 0.02 with H_3PO_4, 2 mol/L, or NaOH, 0.5 mol/L. Add 16 mL absolute ethanol. Mix. Filter and degas before use. Store tightly capped. This solution is stable for 1 month at room temperature.

Instrumentation

A commercially available HPLC system, equipped with a 4.6 mm I.D. > 25 cm reversed-phase C_{18} column (average particle diameter, 5 µm), and either a glassy-carbon or porous-graphite cell, adaptable for use in electrochemical detection, is required for this method.

Procedure

Sample Preparation

1. Pipette 3.0 mL of calibrators, controls, and patient urine samples into labeled 16 × 150-mm tubes.
2. To each tube, add 200 µL of the internal standard solution (iso-VMA), 5.0 mL of acetate buffer (0.08 mol/L, pH 6.1), and 0.1 mL NaOH (0.5 mol/L).
3. Mix well and check pH. pH must be in the range of 5.0 to 7.0. If necessary, adjust pH with 0.1-mL aliquots of NaOH (0.5 mol/L) or acetic acid (2 mol/L).
4. Label one anion-exchange resin column for each calibrator, control, and urine sample to be run. Prepare the columns, about five or six at a time, by shaking them up and down until the resin is completely suspended.
5. Insert each column into a suitable support rack and allow the resin to settle.
6. Remove caps, snap off the tips, and allow the columns to drain into a waste drainage tray.
7. Rinse each column three times with 5 mL of acetate buffer (0.08 mol/L, pH 6.1). Discard the eluates.
8. Quantitatively transfer urine samples into the appropriate columns and allow to drain completely.
9. Rinse each sample tube with 5 mL of acetate buffer. Apply the rinse solution to the respective columns and allow to drain completely.
10. Wash each column with 9.0 mL of wash reagent and allow to drain completely.
11. Replace the drainage tray with a rack containing clean 16 × 150-mm tubes. Make sure that columns are located above marked tubes so that sample will not be spilled.

Sample Analysis

12. Dispense two 9-mL portions of elution reagent into each column. Collect the eluates. Allow the columns to drain completely, discard columns, cover tubes with Parafilm, and mix the tubes thoroughly. (Note: The eluates may be stored overnight at room temperature and at −20 °C for longer periods of storage.)

METHOD 29-8 Determination of Urinary Vanillylmandelic Acid by HPLC/EC—cont'd

13. Establish the optimal operating conditions of the chromatographic and detection systems. Suggested conditions for a dual-cell porous graphite electrochemical detector are as follows:

Flow rate:	2.0 mL/min
Potential of detector cell No. 1:	180 mV
Potential of detector cell No. 2:	410 mV
Chart speed:	1.0 cm/min

14. Inject 20 µL each of calibrator, control, and patient sample onto the HPLC column. Figure A29-6 shows a representative chromatogram of VMA extracted from human urine.

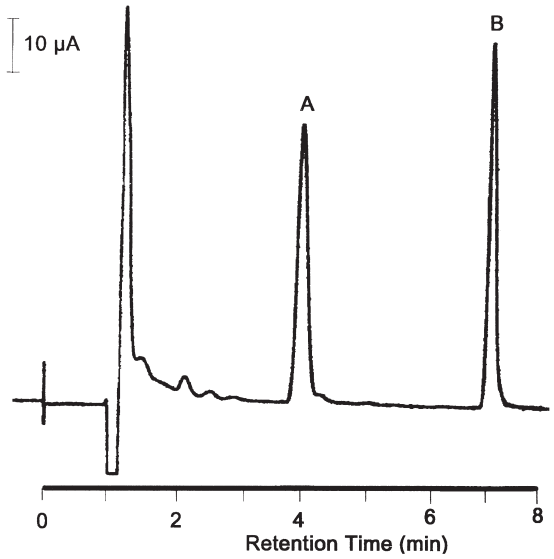

Figure A29-6 Representative chromatogram of vanillylmandelic acid (VMA) extracted from human urine. VMA **(A)** and iso-VMA **(B)** retention are identified on the chromatogram.

Calculations

1. Identify VMA and internal standard peaks based on relative retention times (in minutes). Measure peak heights directly from the chromatographic tracings or obtain from the HPLC data processing system.
2. Calculate peak height ratios for each urine sample, urine control, and calibrator (peak height of VMA/peak height of internal standard).
3. Establish a linear regression curve from peak height ratios using the data obtained from the 5-, 10-, and 20-mg/L calibrators.
4. From the VMA calibrator curve, determine the concentrations of unknowns (mg/L).
5. Calculate 24-hour VMA excretion by multiplying VMA concentration (mg/L) by 24-hour urine volume (L).
6. Calculate VMA excretion normalized for creatinine excretion by dividing VMA concentration (mg/L) by urine creatinine (g/L).

Reference Intervals

Age (yr)	mg/d	µmol/d	mg/g Creatinine	mmol/mol Creatinine
3-6	1.0-2.6	5-13	4.0-10.8	2.3-6.2
6-10	2.0-3.2	10-16	4.0-7.5	2.3-4.3
10-16	2.3-5.2	12-26	3.0-8.8	1.7-5.0
16-83	1.4-6.5	7-33

METHOD 29-9 Determination of Urinary Vanillylmandelic Acid by LC-MS/MS

Submitted by Mark J. Magera, M.A., Dietrich Matern, M.D., and Piero Rinaldo, M.D., Ph.D.
Department of Laboratory Medicine and Pathology, Mayo Clinic and Foundation, Rochester, Minn

Principle

Hydrophilic-lipophilic balance (HLB) solid phase extraction (SPE) is performed on a 1 mL aliquot of either a 24-hour or random urine collection. The SPE column is eluted with 1 mL of methanol. The eluate is evaporated at 30 °C under nitrogen, and the residue reconstituted in 1 mL of a mobile phase consisting of 15% methanol in 0.05% aqueous formic acid. Liquid chromatography-tandem mass spectrometry (LC-MS/MS) is performed by injecting 10 µL of the reconstituted specimen onto an AmideC16 HPLC column. The mobile phase flow rate is 1.0 mL/min, with the LC column effluent flow diverted so that approximately 200 µL/min is delivered to the MS/MS electrospray probe tip. VMA elutes apart from the bulk of the specimen matrix at a retention time of approximately 1.5 minutes. VMA is quantitated using a stable isotope labeled internal standard ($^2H_3$-VMA) from calibration over a concentration range 1.03 to 20 mg/L.

Specimen Collection and Storage

The preferred specimen is a 24-hour urine collected into 25 mL of 50% glacial acetic acid.

For low urine volumes, and infants and children under the age of 5 years, use 15 mL of 50% glacial acetic acid. Boric, nitric, and hydrochloric acids are also acceptable preservatives if the pH of the collected specimen is in the range 1 to 5. A random or 4-hour urine collection is acceptable on pediatric (up to 14 years) submissions if sent to the laboratory immediately after collection. Random urine samples collected on filter paper are also acceptable, but the

METHOD 29-9 Determination of Urinary Vanillylmandelic Acid by LC-MS/MS—cont'd

sensitivity of the method is greater on an aliquot from a 24-hour specimen than on random specimens or dried urine on filter paper. Dried filter paper specimens also typically exhibit more variability.

Reagents

1. Methanol, HPLC grade.
2. Formic acid (HCOOH), 98% to 100%, analytical ACS reagent grade.
3. LC-MS/MS mobile phase, 15% methanol in 0.05% aqueous formic acid. Prepare as needed by mixing 150 mL of methanol with 850 mL of reverse-osmosis water and add 0.50 mL of formic acid, mixing well.
4. VMA internal standard (VMA-IS), 0.500 mg/mL. Prepare by dissolving 5.0 mg of vanillylmandelic acid-ring-$^2H_3$ in 10 mL of 0.1 mol/L HCl in a volumetric flask. Store refrigerated. Stable for 6 months.
5. VMA stock calibrator, 1.00 mg/mL. Prepare by dissolving 10.0 mg VMA in 10 mL of 0.1 mol/L HCl in a volumetric flask. Store refrigerated. Stable for 6 months.
6. VMA working calibrator, 20 mg/L. Prepare by diluting 2.0 mL VMA stock calibrator to 100 mL with reverse-osmosis water in a volumetric flask, mixing well. Store refrigerated. Stable for 6 months.
7. Hydrochloric acid, concentrated, analytical grade.
8. Hydrochloric acid, 0.1 mol/L. Prepare by diluting 4.2 mL concentrated HCl to 500 mL with reverse-osmosis water in a volumetric flask, mixing well. Store at room temperature. Stable indefinitely.

Instrumentation

A commercially available bench-top tandem mass spectrometer (Applied Biosystems/SCIEX API 2000 MS/MS with Turbo IonSpray interface source, or equivalent) is suitable, accompanied by HPLC pump and autosampler (Perkin Elmer [PE] Series 200 isocratic LC pump, PE Series 200 LC autosampler, or equivalent). The HPLC column is a Discovery RP-AmideC16 (Supelco) 5 cm × 4.6 mm, 5 µm particle size. SPE columns are Oasis HLB (Waters, No. WAT094225) 1 mL containing 30 mg sorbent packing. Additional equipment used includes an automated SPE sample processor (Gilson ASPEC, or equivalent) and an evaporator (Zymark Turbo-Vap).

Quality Control

Two controls (normal, elevated) are included in every run. Both urine controls are prepared in-house. Urine containing acetic acid preservative is obtained (approximately 2 L per control). The normal urine control is prepared by simply aliquoting and freezing the urine. Normal urine VMA is generally 1 to 4 mg/L. The elevated urine control is prepared by spiking the urine with approximately 18 mL of the VMA stock calibrator per liter of urine. The target range is approximately 15 mg/L. The spiked urine is mixed well, aliquoted, and stored frozen. Controls are stable for 2 years when kept frozen. The mean VMA and standard deviation are calculated from a minimum of 10 interassay values for each control. Routine assay control values are entered into a spreadsheet (MS Excel) that automatically plots the value in relation to the mean. As a general rule, control values that fall within ±2 SD of the mean are acceptable and require no further action. Any control values that are >2 SD and shifts/trends require review by a supervisor or designee, and a completed VMA Quality Report if indicated. Any control values that are >3 SD require a completed VMA Quality Report and the review of a supervisor or designee. The laboratory QC designee performs monthly compilation, review, and sign off of control values. The final review of the control spreadsheets is performed by one of the laboratory supervisory staff on a monthly basis.

Procedure

HPLC Operating Parameters

1. LC-MS/MS HPLC pump
   Mobile phase flow rate: 1.0 mL/min
   Pressure limit: set at 3000 psi
   Refer to manual for maintenance and trouble shooting of pump problems
2. LC-MS/MS Autosampler
   Injection volume = 10 µL

MS/MS Operating Parameters

1. Electrospray source voltage = −5000 V
2. Source assist gas (zero grade air) = setting 40
3. Source drying gas (zero grade air) = setting 40
4. Source temperature = 280 °C
5. Orifice = −51 V
6. Collision energy = 27 V
7. Collision gas (nitrogen) = setting 3
8. Q1/Q3 resolution = unit mass (0.7 FWHM)
9. Selected reaction monitoring (SRM) mode transitions (Q1/Q3):
   VMA = m/z 197 to m/z 137
   $^2H_3$-VMA = m/z 200 to m/z 140

Sample Analysis

1. Check the samples for acceptable pH. Properly collected specimens will have a pH in the range 1 to 5. Collect an aliquot of urine on pediatric samples (<15 years) for creatinine determination. Urine-soaked filter paper specimens can be analyzed after reconstitution of the urine in reverse-osmosis water, results being expressed as µg/mg creatinine. The method for reconstitution is as follows: Cut a strip from the filter paper about 4 cm wide. Fan-fold the strip and place it into a 10-mL glass screw-capped test tube. For dried urine specimens that appear visually "dilute," a 6-cm wide strip may be used. Add about 10 mL of RO water (water produced by reverse-osmosis) to the vial and cap. Let the urine elute from the filter paper in the vial at room temperature for at least 15 minutes, inverting occasionally. Do not shake; vigorous shaking or vortex is not advised as it tends to cause the filter paper to disintegrate, making subsequent steps difficult. After elution, aliquot the reconstituted specimen for creatinine determination, and use as directed in the subsequent steps.
2. To a 10- × 75-mm tube, add 10 µL of VMA-IS; 600 µL of urine sample, or reconstituted urine from filter paper; and 600 µL of RO water. Vortex to mix.
3. The sample tubes are now ready for automated SPE. Using an automatic processor (Gilson ASPEC, or similar device), the SPE columns are conditioned by adding 1 mL methanol, which is allowed to drain through, followed by 1 mL of reverse-osmosis water. A 1-mL aliquot of the diluted urine specimen is added to the SPE column and allowed to drain through. Following a wash with 0.5 mL of reverse-osmosis water, VMA and $^2H_3$-VMA are eluted in 1 mL of methanol.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 29-9 Determination of Urinary Vanillylmandelic Acid by LC-MS/MS—cont'd

4. The eluate tubes are removed from the processor and placed in an evaporator with a water bath at 30 °C under a gentle stream of nitrogen. Evaporate the eluate tubes just to dry.
5. Remove the eluate tubes from the evaporator and let them cool to room temperature briefly. Add 1.0 mL of VMA LC-MS/MS mobile phase. Vortex to dissolve the residue and mix well. Transfer a 200-µL aliquot of the solution to an autosampler vial and cap. Samples are now ready for analysis.
   Note: For specimens that are <0.01 mg/L, the amount of mobile phase used to reconstitute can be decreased to 100 µL.

Calculations

A 7-point calibration curve is run each time that a new internal standard solution (VMA-IS) is prepared. The calibrator concentrations are 1.03, 2.08, 4.17, 8.33, 12.50, 16.7, and 20.0 mg/L of VMA. The amount of VMA-IS added to each sample is 2.5 mg/L. Normal and elevated VMA controls are calculated against each new calibration and the current QC mean to validate the new calibration. Both controls must also be acceptable to validate the new calibration. VMA concentrations greater than 20 mg/L will be repeated at a dilution with water. The table below indicates how to prepare the calibrators, which are then prepared by SPE as for urine specimens.

STD	VMA-IS, µL	VMA Working Calibrator, µL	RO Water, µL	mg VMA	Theoretical Ratio
1	10	62	1138	1.03	0.2500
2	10	125	1075	2.08	0.5000
3	10	250	950	4.17	1.0000
4	10	500	700	8.33	2.0000
5	10	750	450	12.50	3.0000
6	10	1000	200	16.67	4.0000
7	10	1200	0	20.0	4.800

Comments

1. Any sample with a value <0.01 mg/L is repeated with a 100 µL mobile phase reconstitution volume.
2. Any value >20 mg/L must be diluted and brought into the linearity range. Subsequent results will be multiplied times the appropriate dilution factor and the results reported accordingly.
3. Quantitation of VMA has been valuable in the diagnosis and follow-up of patients with pheochromocytoma and related neurogenic tumors.
4. A blank (reverse-osmosis water substituted for urine sample) will be run after the elevated control in each analysis batch and reviewed for potential autosampler carryover.

Reference Intervals

Age	VMA, urine
<1 year	<27 µg VMA/mg Creatinine
≥1 year	<18
2-4 years	<13
5-9 years	<8.5
10-14 years	<7
Adults	<8 mg VMA/24 hours

METHOD 29-10 Determination of Urinary Homovanillic Acid (3-Methoxy-4-Hydroxyphenylacetic Acid) by HPLC/EC

Submitted by Thomas G. Rosano, Ph.D.
Department of Pathology and Laboratory Medicine, Albany Medical College and Hospital, Albany, N.Y.

Principle

An aliquot of urine is mixed with an internal standard (iso-VMA) and then applied to a strongly basic anion-exchange resin that has been preconditioned with an acetate buffer. HVA is eluted with acetic acid in ethanol and subsequently resolved by reversed-phase HPLC under optimized isocratic conditions. The HVA concentration is determined electrochemically using an amperometric detection system.

Specimen Collection and Storage

A complete 24-hour urine collection is recommended because variations in HVA excretion occur throughout the day. Shorter collection times may be useful provided that HVA results are expressed per milligram of creatinine. The urine should be collected in a clean container that contains acid as a stabilizing preservative (e.g., 10 mL of HCl, 6 mol/L, for a 24-hour collection). The specimen should be refrigerated during collection. The total urine volume is measured and recorded; a 50-mL aliquot is stored at 4 °C until the test is performed or may be frozen and stored indefinitely. No dietary restrictions during urine collection are necessary. Urine may also be collected on filter paper.

Reagents

1. Resin column filled with strongly basic anion-exchange resin (Bio-Rad Laboratories, Catalog No. 195-5005).
2. Sodium acetate, 2 mol/L. Dissolve 82 g of sodium acetate in distilled water to a final volume of 0.5 L. This solution is stable for 1 month at 4 °C.
3. Acetic acid, 2 mol/L. Dilute 57.5 mL of glacial acetic acid in distilled water to a final volume of 0.5 L.
4. KH_2PO_4, 1 mol/L. Dissolve 68.05 g KH_2PO_4 in distilled water to a final volume of 0.5 L. This solution is stable for 1 month at 4 °C.
5. NaOH, 0.5 mol/L. Dissolve 2.0 g NaOH in distilled water and dilute to 0.1 L. Store tightly capped.
6. HCl, 0.05 mol/L. Dilute 1.0 mL of concentrated HCl in distilled water to a final volume of 0.25 L.

Continued

METHOD 29-10 Determination of Urinary Homovanillic Acid (3-Methoxy-4-Hydroxyphenylacetic Acid) by HPLC/EC—cont'd

7. Acetate buffer, 0.08 mol/L, pH 6.1. Mix 40 mL of sodium acetate, 2 mol/L, with 1.2 mL of acetic acid, 2 mol/L. Dilute to 1 L. Adjust the pH to 6.10 ± 0.05 with acetic acid, 2 mol/L, or NaOH, 0.5 mol/L. This solution is stable for 1 month at 4 °C.
8. Elution reagent, acetic acid/ethanol. Mix 250 mL acetic acid (2 mol/L), 250 mL H_2O, and 500 mL ethanol (95%). This solution is stable for 1 month at 4 °C.
9. HVA calibration solutions (Bio-Rad Laboratories, Catalog No. 195-5006). Reconstitute with 25 mL 0.05 mmol/L HCl. Let stand 10 minutes, then gently agitate to dissolve. Stable 30 days at 2 °C to 8 °C.
10. Internal standard, iso-VMA (Bio-Rad Laboratories, Catalog No. 195-5213). Reconstitute with 25 mL of methanol. Agitate gently to dissolve. Stable 3 months at 2 °C to 8 °C.
11. Mobile phase, ethanol/phosphate buffer. Combine 965 mL of deionized H_2O, 20 mL 1 mmol/L KH_2PO_4, and 15 mL 2 mol/L phosphoric acid. Mix well and allow 5 minutes for equilibration. Check pH on a pH meter. If necessary, adjust pH to 2.3 ±0.05 with 2 mol/L phosphoric acid or 0.5 mol/L sodium hydroxide. Add 90 mL of ethanol (100%), 5 mL methanol, and 25 mL isopropanol and mix another 2 to 3 minutes. Filter by suction through a 0.45-µm filter and store capped at 2 °C to 8 °C.

Instrumentation

A commercially available HPLC system, equipped with a 4.6-mm I.D. × 25-cm, reversed-phase C_{18} column (average particle diameter, 5 µm), and either a glassy-carbon or porous-graphite cells, adaptable for use in electrochemical detection, is required.

Procedure

Sample Preparation

1. Pipette 3.0 mL of calibrators, controls, and patient urine samples into labeled 16 × 150-mm tubes.
2. To each tube, add 200 µL of the internal standard solution (iso-VMA), 5.0 mL of acetate buffer (0.08 mol/L, pH 6.1), and 0.1 mL NaOH (0.5 mol/L).
3. Mix well and check pH. pH must be in the range of 5.0 to 7.0. If necessary, adjust pH with 0.1-mL aliquots of NaOH (0.5 mol/L) or acetic acid (2 mol/L).

Isolation of Analyte

4. Label one anion-exchange resin column for each calibrator, control, and urine sample to be run. Prepare the columns, about five or six at a time, by shaking them up and down until the resin is completely suspended.
5. Insert each column into a suitable support rack and allow the resin to settle.
6. Remove caps, snap off the tips, and allow the columns to drain into a waste drainage tray.
7. Rinse each column three times with 5 mL of acetate buffer (0.08 mol/L, pH 6.1). Discard the eluates.
8. Quantitatively transfer urine samples into the appropriate columns and allow to drain completely.
9. Rinse each sample tube with 5 mL of acetate buffer. Apply the rinse solution to the respective columns and allow to drain completely.
10. Replace the drainage tray with a rack containing clean 16 × 150-mm tubes. Make sure that columns are located above marked tubes so that sample will not be spilled.
11. Dispense 2 × 6 mL of elution reagent into each column and allow column to drain completely.
    Note: The eluates may be stored overnight at room temperature and at −20 °C for longer periods of storage.

High-Performance Liquid Chromatography Analysis

12. Establish the optimal operating conditions of the chromatographic and detection systems. Suggested conditions for a dual-cell porous graphite electrochemical detector are as follows:

Flow rate:	1.0 mL/min
Potential of detector cell No.1:	180 mV
Potential of detector cell No.2:	460 mV
Chart speed:	1.0 cm/min

13. Inject 20 µL each of calibrator, control, and patient sample onto the HPLC column. Figure A29-7 shows a representative chromatogram of HVA extracted from human urine.

Calculations

1. Identify HVA and internal standard peaks based on relative retention times (in minutes). Measure peak heights directly from the chromatographic tracings or obtain from the HPLC data processing system.
2. Calculate peak height ratios for each urine sample, urine control, and calibrator (peak height of HMA/peak height of internal standard).
3. Establish a linear regression curve from peak height ratios using the data obtained from the 5-, 10-, and 20-mg/L calibrators.

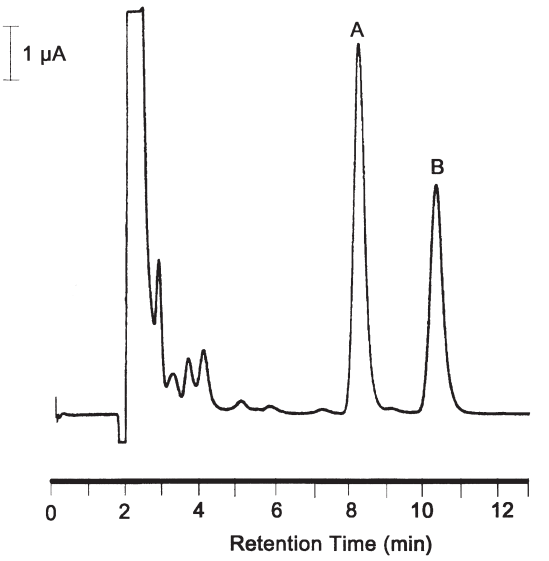

Figure A29-7 Representative chromatogram of homovanillic acid (HVA) extracted from human urine. HVA **(A)** and iso-HVA **(B)** retention are identified on the chromatogram.

METHOD 29-10 Determination of Urinary Homovanillic Acid (3-Methoxy-4-Hydroxyphenylacetic Acid) by HPLC/EC—cont'd

4. From the HVA calibrator curve, determine the concentrations of unknowns (mg/L).
5. Calculate 24-hour HVA excretion by multiplying HVA concentration (mg/L) by 24-hour urine volume (L).
6. Calculate HVA excretion normalized for creatinine excretion by dividing HVA concentration (mg/L) by urine creatinine (g/L).

Reference Intervals

Age (yr)	mg/d	µmol/d	mg/g Creatinine	mmol/mol Creatinine
3-6	1.4-4.3	8-24	5.4-15.5	3.4-9.6
6-10	2.1-4.7	12-26	4.4-11.5	2.7-7.1
10-16	2.4-8.7	13-48	3.3-10.3	2.0-6.4
16-83	1.4-8.8	8-48

METHOD 29-11 Determination of Urinary Homovanillic Acid by LC-MS/MS

Submitted by Mark J. Magera, M.A., Dietrich Matern, M.D., and Piero Rinaldo, M.D., Ph.D.
Department of Laboratory Medicine and Pathology, Mayo Clinic and Foundation, Rochester, Minn.

Principle

Octadecyl (C_{18}) solid phase extraction (SPE) is performed on a 1 mL aliquot of either a 24-hour or random urine collection. The SPE column is eluted with 1 mL of methanol. The eluate is evaporated at 30 °C to 40 °C under nitrogen and the residue reconstituted in 1 mL of 30% acetonitrile in 0.05% aqueous acetic acid. Liquid chromatography-tandem mass spectrometry (LC-MS/MS) is performed by autosampler injection of 10 µL of the reconstituted specimen onto an AmideC16 HPLC column. The mobile phase flow rate is 1.0 mL/min, with the LC column effluent flow diverted so that approximately 200 µL/min is delivered to the MS/MS electrospray probe tip. Homovanillic acid (HVA) elutes apart from the bulk of the specimen matrix at a retention time of approximately 1.5 minutes. HVA is quantitated using a custom synthesized stable isotope labeled internal standard ($^{13}C_6{}^{18}O$-HVA) from calibration over a concentration range 0.52 to 16.7 mg/L.

Specimen Collection and Storage

The preferred specimen is a 24-hour urine collected into 25 mL of 50% glacial acetic acid.

For low urine volumes, and infants and children under the age of 5 years, use 15 mL of 50% glacial acetic acid. Boric, nitric, and hydrochloric acids are also acceptable preservatives if the pH of the collected specimen is in the range 1 to 5. A random or 4-hour urine collection is acceptable on pediatric (up to 14 years) submissions if sent to the laboratory immediately after collection. Random urine samples collected on filter paper are also acceptable, but the sensitivity of the method is greater on an aliquot from a 24-hour specimen than on random specimens or dried urine on filter paper. Dried filter paper specimens also typically exhibit more variability.

Reagents

1. Acetonitrile, HPLC grade.
2. Acetic acid, glacial (CH_3COOH), analytical grade.
3. LC-MS/MS mobile phase, 30% acetonitrile in 0.05% aqueous acetic acid. Prepare as necessary by mixing 600 mL of acetonitrile with 1400 mL of reverse-osmosis water and add 1 mL glacial acetic acid, mixing well.
4. HVA internal standard (HVA-IS), 0.500 mg/mL. Prepare by dissolving 5.0 mg of $^{13}C_6{}^{18}O$-HVA in 10 mL of 0.1 mol/L HCl in a volumetric flask. Store refrigerated. Stable for 3 months.
5. HVA stock calibrator, 1.00 mg/mL. Prepare by dissolving 10.0 mg HVA in 10 mL of 0.1 mol/L HCl in a volumetric flask. Store refrigerated. Stable for 3 months.
6. HVA working calibrator, 20 mg/L. Prepare by diluting 2.0 mL HVA stock calibrator to 100 mL with reverse-osmosis water in a volumetric flask, mixing well. Store refrigerated. Stable for 3 months.
7. Hydrochloric acid, concentrated, analytical grade.
8. Hydrochloric acid, 0.1 mol/L. Prepare by diluting 4.2 mL concentrated HCl to 500 mL with reverse-osmosis water in a volumetric flask, mixing well. Store at room temperature. Stable indefinitely.

Instrumentation

A commercially available bench-top tandem mass spectrometer (Applied Biosystems/SCIEX API 2000 MS/MS with Turbo IonSpray interface source, or equivalent) is suitable, accompanied by HPLC pump and autosampler (Perkin Elmer [PE] Series 200 isocratic LC pump, PE Series 200 LC autosampler, or equivalent). The HPLC column is a Discovery RP-AmideC16 (Supelco) 5 cm × 4.6 mm, 5 µm particle size. Several SPE columns have been evaluated and validated: (1) Bond Elut C_{18} (Varian No. 1210-2001), 1mL (100mg); (2) Oasis HLB, (Waters) 1 mL (30 mg); and (3) Strata X, 33 µm polymeric sorbent (Phenomenex No. 8B-S100-TAK), 1mL (30 mg). Additional equipment used includes an automated SPE sample processor (Gilson ASPEC, or equivalent), and an evaporator (Zymark Turbo-Vap).

METHOD 29-11 Determination of Urinary Homovanillic Acid by LC-MS/MS—cont'd

Quality Control

Two controls (normal, elevated) are included in every run. Both urine controls are prepared in-house. Urine containing acetic acid preservative is obtained (approximately 2 L per control). The normal urine control is prepared by simply aliquoting and freezing the urine. Normal urine HVA is generally 1 to 4 mg/L. The elevated urine control is prepared by spiking the urine with approximately 18 mL of the HVA stock calibrator per liter of urine. The target range is approximately 15 mg/L. The spiked urine is mixed well, aliquoted, and stored frozen. Controls are stable for 2 years when kept frozen. The mean HVA and standard deviation are calculated from a minimum of 10 interassay values for each control. Routine assay control values are entered into a spreadsheet (MS Excel) that automatically plots the value in relation to the mean. As a general rule, control values that fall within ± 2 SD of the mean are acceptable and require no further action. Any control values that are >2 SD and shifts/trends require review by a supervisor or designee, and a completed HVA Quality Report if indicated. Any control values that are >3 SD require a completed HVA Quality Report and the review of a supervisor or designee. The laboratory QC designee performs monthly compilation, review, and sign off of control values. The final review of the control spreadsheets is performed by one of the laboratory supervisory staff on a monthly basis.

Procedure

HPLC Operating Parameters

1. LC-MS/MS HPLC pump
   Mobile phase flow rate: 1.0 mL/min
   Pressure limit: set at 3000 psi
   Refer to manual for maintenance and trouble shooting of pump problems
2. LC-MS/MS autosampler
   Injection volume = 10 µL

MS/MS Operating Parameters

1. Electrospray source voltage = −5000 V
2. Source assist gas (zero grade air) = setting 40
3. Source drying gas (zero grade air) = setting 40
4. Source temperature = 250 °C
5. Orifice = −27 V
6. Collision energy = 15 V
7. Collision gas (nitrogen) = setting 3
8. Q1/Q3 resolution = unit mass (0.7 FWHM)
9. Selected reaction monitoring (SRM) mode transitions (Q1/Q3):
   HVA = *m/z* 181 to *m/z* 137
   $^{13}C_6{}^{18}O$-HVA = *m/z* 189 to *m/z* 145

Sample Analysis

1. Check the samples for acceptable pH. Properly collected specimens will have a pH in the range 1 to 5. Collect an aliquot of urine on pediatric samples (<15 yr) for creatinine determination. Urine-soaked filter paper specimens can be analyzed after reconstitution of the urine in reverse-osmosis water, results being expressed as µg/mg creatinine. The method for reconstitution is as follows: Cut a strip from the filter paper, about 4 cm wide. Fan-fold the strip and place it into a 10 mL glass screw-capped test tube. For dried urine specimens that appear visually "dilute," a 6-cm wide strip may be used. Add about 10 mL of RO water (water prepared by reverse-osmosis) to the vial and cap. Let the urine elute from the filter paper in the vial at room temperature for at least 15 minutes, inverting occasionally. Do not shake as vigorous shaking or vortex tends to cause the filter paper to disintegrate, making subsequent steps difficult. After elution, aliquot the reconstituted specimen for creatinine determination, and use as directed in the subsequent steps.
2. To a 10- × 75-mm tube, add 10 µL of HVA-IS, 1200 µL of urine sample, or reconstituted urine from filter paper. Vortex to mix.
3. The sample tubes are now ready for automated SPE. Using an automatic processor (Gilson ASPEC, or similar device), the SPE columns are conditioned by the adding 1 mL methanol, which is allowed to drain through, followed by 1 mL of reverse-osmosis water. A 1 mL aliquot of the diluted urine specimen is added to the SPE column and allowed to drain through. Following a wash with 0.5 mL of reverse-osmosis water, HVA and $^{13}C_6{}^{18}O$-HVA are eluted in 1 mL of methanol.
4. The eluate tubes are removed from the processor and placed in an evaporator with a water bath at 30 °C under a gentle stream of nitrogen. Evaporate the eluate tubes just to dry.
5. Remove the eluate tubes from the evaporator and let them cool to room temperature briefly. Add 1.0 mL of HVA LC-MS/MS mobile phase. Vortex to dissolve the residue and mix well. Transfer a 200 µL aliquot of the solution to an autosampler vial and cap. Samples are now ready for analysis.
   Note: For specimens that are <0.01 mg/L, the amount of mobile phase used to reconstitute can be decreased to 100 µL.

Chromatograms

METHOD 29-11 Determination of Urinary Homovanillic Acid by LC-MS/MS—cont'd

Calculations

A 7-point calibration curve is run each time that a new internal standard solution (HVA-IS) is prepared. The calibrator concentrations are 0.52, 1.04, 2.08, 4.16, 8.33, 16.7, and 20.0 mg/L of HVA. The amount of HVA-IS added to each sample is 4.17 mg/L. Normal and elevated HVA controls are calculated against each new calibration and the current QC mean to validate the new calibration. Both controls must also be acceptable to validate the new calibration. HVA concentrations greater than 20 mg/L will be repeated at a dilution with water. The table below indicates how to prepare the calibrators, which are then prepared by SPE as for urine specimens.

STD	HVA-IS, µL	HVA Working Calibrator, µL	OR Water, µL	mg/L HVA	Theoretical Ratio
1	10	31	1169	0.52	0.1250
2	10	62	1138	1.04	0.2500
3	10	125	1075	2.08	0.5000
4	10	250	950	4.16	1.0000
5	10	500	700	8.33	2.0000
6	10	1000	200	16.7	4.0000
7	10	1200	0	20.0	4.8000

Comments

1. Any sample with a value <0.01 mg/L is repeated with a 100-µL mobile phase reconstitution volume.
2. Any value >20 mg/L must be diluted and brought into the linearity range. Subsequent results will be multiplied times the appropriate dilution factor and the results reported accordingly.
3. Urinary HVA, a metabolite of dopamine, is frequently measured to support a diagnosis of neuroblastoma and pheochromocytoma and is useful in monitoring treated patients.
4. A blank (reverse-osmosis water substituted for urine sample) will be run after the elevated control in each analysis batch and reviewed for potential autosampler carryover.
5. Administration of L-dopa may result in elevated HVA values.

Reference Intervals

Age	HVA, urine
<1 yr	<35 µg/mg creatinine
1-2	<23
2-5	<13.5
5-l0	<9.0
10-15	<12.0
Adult	<8 mg/24 hr

METHOD 29-12 Determination of Urinary 5-Hydroxyindoleacetic Acid by Quantitative HPLC

Submitted by Ronald J. Whitley, Ph.D. Department of Pathology and Laboratory Medicine, College of Medicine, University of Kentucky Medical Center, Lexington, Ky.

Principle

Diluted urine samples are analyzed without sample preparation using reversed-phase HPLC with electrochemical detection.

Specimen Collection and Storage

A 24-hour urine specimen is recommended, since 5-HIAA concentrations in random urine specimens are extremely variable. Shorter (or longer) collection times may be acceptable provided results are expressed per milligram of creatinine. Because 5-HIAA is light sensitive, urine should be collected in 2-L brown polypropylene containers. The specimen may be collected with or without preservatives. In view of conflicting reports, however, the addition of a stabilizing preservative to the urine container is encouraged (e.g., 0.5 g boric acid; 10 mL HCl, 6 mol/L; 25 mL glacial acetic acid). Most importantly, the specimen should be refrigerated during collection. On receipt in the laboratory, the urine specimen is thoroughly mixed and the total volume measured and recorded. If the specimen is not collected with an acid preservative, then the pH of the urine may now be adjusted to between 2 and 3 by addition of HCl, 6 mol/L. Acidified urine can be stored at 4 °C for 2 to 4 weeks and for longer periods of time at −20 °C. False-negative results may occur in patients taking phenothiazine drugs. The ingestion of foods high in hydroxyindole content (e.g., bananas, avocados, red plums, eggplants, pineapples, kiwi fruit, walnuts, hickory nuts, and tomatoes) or cough medications containing glycerol guaiacolate may lead to false-positive results. Therefore these drugs and foods should be restricted 3 to 4 days before and during the collection.

Reagents

1. Acetic acid, 6 mol/L. Dilute 34.5 mL of glacial acetic acid to 100 mL with distilled water. Stable for 1 year at room temperature.
2. Acetate buffer, 0.1 mol/L, pH 5. Transfer 1.5 mL of acetic acid, 6 mol/L, and 1.3 g of sodium acetate to a 250-mL volumetric flask. Dissolve and dilute to the mark with distilled water. Stable for 1 year at room temperature.
3. 5-HIAA calibrators.
   a. Stock calibrator, 500 mg/L. Weigh and transfer 25 mg of 5-HIAA to a 50-mL volumetric flask. Dissolve in 40 mL of water. Adjust the pH to <3 with concentrated HCl. Dilute to the mark with water. Store in a dark brown bottle at 4 °C. Discard after 1 month.
   b. Working calibrator, 50 mg/L. Dilute 1 mL of the stock solution to 10 mL with water. Prepare fresh before use.
4. Mobile phase. Add the following reagents to 1500 mL of distilled water: 54 mL of concentrated NH_4OH, 69 mL of glacial acetic acid, and 0.2 g of Na_2EDTA. Adjust pH to 5.1 with either acetic acid

METHOD 29-12 Determination of Urinary 5-Hydroxyindoleacetic Acid by Quantitative HPLC—cont'd

(6 mol/L) or NH_4OH (6 mol/L). Then add 20 mL of methanol and 20 mL of acetonitrile. Dilute to 2 L with distilled water, mix, and filter. Degas for 15 minutes. Prepare fresh daily.

Instrumentation
A commercially available HPLC system equipped with a 25-cm × 4.6-mm, reversed-phase C_{18} column (average particle diameter 5 µm) and a glassy-carbon electrochemical detector is suitable.

Quality Control
Two urine controls are included in every run. For example, Bio-Rad Lyphochek Quantitative Urine Control, Levels 1 and 2 (Bio-Rad Clinical Diagnostics Group, Hercules, Calif.) are reconstituted each day with distilled water.

Procedure
1. Pipette 4 mL of sodium acetate buffer into labeled 13 × 100-mm tubes.
2. Add 100 µL of working HIAA calibrator, specimens, and urine controls to their respective tubes. Mix in a vortex mixer.
3. Establish operating conditions of the chromatographic and detection systems. Suggested conditions are:

Potential:	500 mV
Sensitivity:	100 mA/V
Flow rate:	1.0 mL/min
Chart speed:	0.5 cm/min

4. Inject 15 µL of each sample onto the HPLC column.

Chromatogram
Figure A29-9 shows a representative chromatogram of 5-HIAA extracted from urine.

Calculations
1. Identify 5-HIAA based on relative retention times (in minutes). Measure peak heights directly from the chromatographic tracings or obtain from the HPLC data processing system.
2. Calculate concentrations of unknowns:
   $HIAA = H_u/H_c \times C_c$
   where
   HIAA = unknown 5-HIAA concentration (mg/L)
   H_u = peak height of unknown
   H_c = peak height of calibrator
   C_c = concentration of 5-HIAA working calibrator (50 mg/L)
3. Calculate 24-hour 5-HIAA excretion by multiplying 5-HIAA concentration (mg/L) by 24-hour urine volume (L).

Comments
1. Specimens having a concentration greater than 50 mg/L must be diluted with water and repeated.
2. Inclusion of an internal standard may improve assay precision. 5-Hydroxyindole-2-carboxylic acid is available commercially for this purpose and can be added to all assay tubes before HPLC analysis (e.g., 100 µL of a 50-mg/L solution). The composition of the mobile phase, however, may need to be adjusted slightly to resolve the internal standard from interfering substances. Internal standard peaks are identified from the chromatographic tracing, and peak heights are measured. Peak height ratios are then calculated for each urine sample, urine control, and calibrator (peak height of 5-HIAA/peak height of internal standard). These peak height ratios are used to calculate concentrations of unknowns.

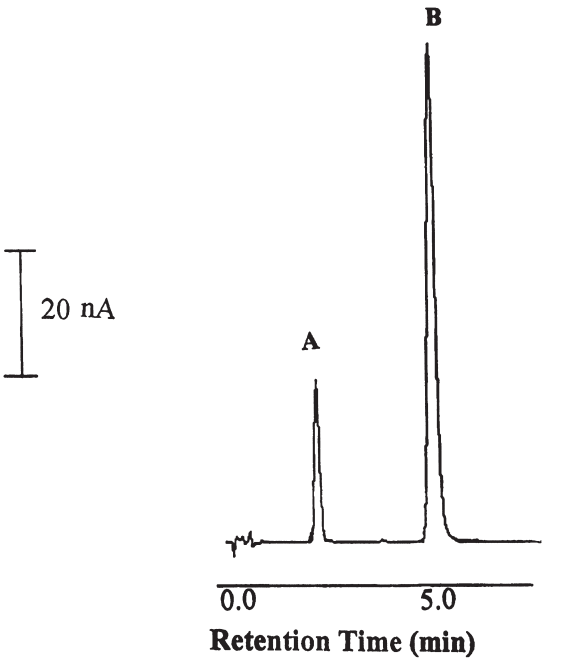

Figure A29-9 Representative chromatogram of 5-hydroxyindoleacetic acid (5-HIAA) extracted from human urine. 5-HIAA **(A)** and internal standard **(B)** retention are identified on the chromatogram.

Reference Intervals
Representative reference intervals for adults using HPLC are as follows:

1-7 mg/d [6-37 µmol/d]
0-6.6 mg/g creatinine [0-3.9 µmol/mmol creatinine]

METHOD 29-13 Determination of Urinary 5-Hydroxyindole-3-Acetic Acid by LC-MS/MS

Submitted by Mark J. Magera, M.A., Dietrich Matern, M.D., and Piero Rinaldo, M.D., Ph.D.
Department of Laboratory Medicine and Pathology, Mayo Clinic and Foundation, Rochester, Minn.

Principle

Octadecyl (C_{18}) solid phase extraction (SPE) is performed on a 0.5-mL aliquot of a 24-hour urine collection. The SPE column is eluted with 1 mL of 20% acetonitrile in 0.05% aqueous formic acid. Liquid chromatography-tandem mass spectrometry (LC-MS/MS) is performed by autosampler injection of 10 µL of the reconstituted specimen onto an AmideC16 HPLC column. The mobile phase flow rate is 1.0 mL/min, with the LC column effluent flow diverted so that approximately 200 µL/min is delivered to the MS/MS electrospray probe tip. 5-hydroxyindole-3-acetic acid (5-HIAA) elutes apart from the bulk of the specimen matrix at a retention time of approximately 1.5 minutes. 5-HIAA is quantitated using a custom synthesized stable isotope labeled internal standard ($^2H_6$-HIAA) from calibration over a concentration range up to 150 mg/L.

Specimen Collection and Storage

The preferred specimen is a 24-hour urine collected into 25 mL of 50% glacial acetic acid.

For low urine volumes, and infants and children under the age of 5 years, use 15 mL of 50% glacial acetic acid. Other urine preservatives are also acceptable, including boric, nitric, and hydrochloric acids along with sodium carbonate, toluene, and thymol. 5-HIAA is stable in properly preserved refrigerated specimens for up to 7 days and stable for long periods if specimens are kept frozen at −20 °C. Spot (random) or nonpreserved urine collections are unacceptable. Foods containing high levels of serotonin—including walnuts, hickory nuts, plantain, pineapple, bananas, kiwi, plums, tomatoes, avocados, dates, grapefruit, cantaloupe, or honeydew melon—should not be consumed for at least 48 hours before urine collection. Additionally, some drugs affecting serotonin levels will affect 5-HIAA levels.

Reagents

1. Methanol, HPLC grade.
2. Acetonitrile, HPLC grade.
3. Formic acid (HCOOH), 98% to 100%, analytical ACS reagent grade.
4. LC-MS/MS mobile phase, 20% acetonitrile in 0.05% aqueous formic acid. Prepare as necessary by mixing 200 mL of acetonitrile with 800 mL of reverse-osmosis water and add 0.500 mL formic acid, mixing well.
5. Acetic acid, glacial (CH_2COOH), analytical grade.
6. Acetic acid, 1%. Prepare by diluting 10 mL of glacial acetic acid to 1000 mL with reverse-osmosis water in a volumetric flask. Store at room temperature. Stable indefinitely.
7. 5-HIAA internal stock standard (HIAA-IS), 1 mg/mL. Prepare by dissolving 25.0 mg of $^2H_6$-HIAA in 25 mL of methanol in a volumetric flask. Store refrigerated. Stable for 6 months.
8. 5-HIAA stock calibrator, 1.00 mg/mL. Prepare by dissolving 100 mg 5-HIAA in 100 mL of 1% acetic acid in a volumetric flask. Store refrigerated. Stable for 6 months.
9. HIAA-IS working calibrator, 10 mg/L. Prepare by diluting 2.0 mL HIAA-IS stock calibrator to 200 mL with 1% acetic acid in a volumetric flask, mixing well. Store refrigerated. Stable for 1 month.
10. 5-HIAA working calibrators. Prepare using the following table. Stable for 3 months when stored refrigerated in amber bottles.

5-HIAA Working Calibrator Conc. (µg/mL)	Amount (mL) of 1 mg/mL Stock 5-HIAA Calibrator	Total Volume (mL) 1% Acetic Acid
Blank (0)		
5	1	200
12.5	1.25	100
25	5	200
150	15	100

Instrumentation

A commercially available bench-top tandem mass spectrometer (Applied Biosystems/SCIEX API 2000 MS/MS with Turbo IonSpray interface source, or equivalent) is suitable, accompanied by HPLC pump and autosampler (Perkin Elmer [PE] Series 200 isocratic LC pump, PE Series 200 LC autosampler, or equivalent). The HPLC column is a Discovery RP-AmideC16 (Supelco) 5 cm × 4.6 mm, 5 µm particle size. Several SPE columns have been evaluated and validated and include: BondElut C_{18} Extraction Cartridges, (Varian No. 1210-2001), 1mL (100mg), Discovery DSC-18 (Supelco No.52602-U) 1 mL (100 mg) and C_{18} SPE Cartridge (Zorbax No.5184-3590), 1 mL (100 mg). The following alternate SPE columns may be used if the eluting solvent in the procedure is substituted with 30% acetonitrile in reverse-osmosis water: Strata C_{18}-E (Phenomenex No. 8B-S001-EAK-S), 1 mL (100 mg), or Oasis HLB (Waters, No. WAT094225), 1 mL (30 mg). Additional equipment used includes an automated SPE sample processor (Gilson ASPEC, or equivalent) and an evaporator (Zymark Turbo-Vap).

Quality Control

Two controls (normal, elevated) are included in every run. Both urine controls are prepared in-house. Urine containing acetic acid preservative is obtained (approximately 2 L per control). The normal urine control is prepared by simply aliquoting and freezing the urine. Normal urine 5-HIAA is generally 1 to 4 mg/L. The elevated urine control is prepared by spiking the urine with approximately 18 mL of the 5-HIAA stock calibrator per liter of urine. The target range is approximately 15 mg/L. The spiked urine is mixed well, aliquoted, and stored frozen. Controls are stable for 2 years when kept frozen. The mean 5-HIAA and standard deviation are calculated from a minimum of 20 interassay values for each control. Routine assay control values are entered into a spreadsheet (MS Excel) that automatically plots the value in relation to the mean. As a general rule, control values that fall within ±2 SD of the mean are acceptable and require no further action. Any control values that are >2 SD and shifts/trends require review by a supervisor or designee, and a completed HIAA Quality Report if indicated. Any control values that are >3 SD require a completed HIAA Quality Report and the review of a supervisor or designee. The laboratory QC designee performs monthly compilation, review, and sign off of control values. The final review of the control spreadsheets is performed by one of the laboratory supervisory staff on a monthly basis.

METHOD 29-13 Determination of Urinary 5-Hydroxyindole-3-Acetic Acid by LC-MS/MS—cont'd

Procedure

HPLC Operating Parameters

1. LC-MS/MS HPLC pump
   Mobile phase flow rate: 1.0 mL/min
   Pressure limit: set at 3000 psi
   Refer to manual for maintenance and trouble shooting of pump problems
2. LC-MS/MS autosampler
   Injection volume = 10 µL

MS/MS Operating Parameters

1. Electrospray source voltage = −5000 V
2. Source assist gas (zero grade air) = setting 30
3. Source drying gas (zero grade air) = setting 55
4. Source temperature = 250 °C
5. Orifice = −36 V
6. Collision energy = 13 V
7. Collision gas (nitrogen) = setting 3
8. Q1/Q3 resolution = unit mass (0.7 FWHM)
9. Selected reaction monitoring (SRM) mode transitions (Q1/Q3):
   5-HIAA = *m/z* 190 to *m/z* 146
   $^{2}H_{6}$-HIAA = *m/z* 196 to *m/z* 152

Sample Analysis

1. To a 10 × 75-mm tube, add 500 µL of working HIAA-IS and 500 µL of urine sample or 5-HIAA calibrator (see Reagents 10.) Vortex to mix.
2. The sample tubes are now ready for automated SPE. Using an automatic processor (Gilson ASPEC, or similar device), the SPE columns are conditioned by adding 1 mL of methanol, which is allowed to drain through, followed by 1 mL of reverse-osmosis water. 1 mL of the diluted urine specimen is added to the SPE column and allowed to drain through. Following a wash with 0.5 mL of reverse-osmosis water, 5-HIAA and $^{2}H_{6}$-HIAA are eluted in one mL of LC-MS/MS mobile phase (see Reagents).
3. Vortex the eluate tubes to dissolve the residue. Transfer a 200-µL aliquot of the solution to an autosampler vial and cap. Samples are now ready for analysis.

Calculations

A 5-point calibration curve is run each time that a new internal standard solution (HIAA-IS) is prepared. The calibrator concentrations are 0.00, 5.00, 12.50, 25.00, and 150.00 µg/mL of 5-HIAA. The amount of HIAA-IS added to each sample is 5 µg. Normal and elevated 5-HIAA controls are calculated against each new calibration and the current QC mean to validate the new calibration. Both controls must also be acceptable to validate the new calibration. 5-HIAA concentrations greater than 150 mg/L will be repeated at a dilution with water. The observed 5-HIAA concentration in mg/L is converted to mg 5-HIAA/24 hours by multiplying by the 24-hour urine volume in liters.

Comments

1. Normally 1% to 3% of dietary tryptophan is metabolized to serotonin. However, as much as 60% of this tryptophan is converted to serotonin in the intestinal carcinoid syndrome, argentaffinoma. 5-HIAA is the major metabolite of serotonin and is excreted in the urine.
2. Any 5-HIAA value >150 mg/L must be diluted and brought into the linearity range. Subsequent results will be multiplied times the appropriate dilution factor and the results reported accordingly. 5-HIAA values less than 0.1 mg/L are reported as <0.1 mg/L.
3. A blank (reverse-osmosis water substituted for urine sample) will be run after the elevated control in each analysis batch and reviewed for potential autosampler carryover.

Reference Intervals

≤6 mg 5-HIAA/24 hours

Gordon S. Fell, Ph.D., F.R.C.Path.,
and T.D.G. Lyon, B.Sc., Ph.D.

QUESTIONS CLINICIANS MAY ASK REGARDING THE STATUS OF INDIVIDUAL NUTRIENTS

1. To what extent has there been adequacy of long-term nutrition?
2. Is the total body content sufficiently low to cause major alterations in structure or function of individual tissue or organs?
3. Has there been a short-term mismatch, either underprovision or overprovision that may put the patient at risk if this continues, but that is not yet causing structural or functional effects?
4. Is any undersupply of such magnitude that there is a current need for nutritional supplements?
5. Has supply been so excessive that a reduction in provision is necessary?
6. If the test were repeated, would it help to indicate the efficacy of the nutritional intervention?
7. If results are particularly abnormal at this time, can they assist in giving an indication of prognosis?
8. Is it possible to use results, either individually or in combination, to indicate relatively minor variations in nutritional status, which may, at some later date, put the patient at risk of a particular disease or group of diseases?

ROLE OF LABORATORY IN NUTRITIONAL ASSESSMENT

Use of laboratory tests will vary considerably, depending on the interest of clinical staff responsible for patients who have nutritional problems as part of their disease state, the local availability of relevant tests, and of course local systems for charging or reimbursement. However, some guidelines can be proposed for good practice, combining knowledge of nutritional requirements with clinical and laboratory assessments:

1. Take a good clinical history to determine the likely risk of an inadequate or unbalanced diet, which might predispose to some form of nutritional deficiency.
2. Perform a careful clinical examination, looking for signs of muscle wasting, fat loss, skin rashes, or other evidence of specific nutritional deficiencies.
3. Where there is evidence of a specific nutritional problem, perform the appropriate laboratory test for confirmation. After the blood sample has been taken, it may be appropriate to commence supplements before results are available. Clinical response to supplements is often a more specific test of deficiency than a plasma concentration.
4. For most patients, provide a well-balanced nutritional intake to prevent the negative effects of correcting only part of the nutritional status.
5. Provide sufficient trace elements and vitamins to prevent clinical deficiency states from occurring. This involves knowledge of requirements in health, modified by metabolic state and increased losses so that the approximate on-going daily requirement can be estimated. This can then be adjusted for the history of the patient, in terms of the probable recent intake and estimated losses, to allow an estimate of the amount required for repletion and maintenance. Most of the commonly used enteral and parenteral products provide some excess of all the trace elements and vitamins in relation to the normal daily requirements. Nonetheless some additional supply

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

may be needed, especially in patients with preexisting substantial depletion or large on-going losses.
6. Attempt to prevent a subclinical deficiency state by using intakes that have been proved to have beneficial clinical effects in controlled clinical studies. There are only a few of these, but where such evidence is available, it should be used.
7. Measure the plasma concentration of zinc, copper, selenium, and folate at the start of a period of nutritional support and every 2 to 4 weeks thereafter, depending upon the type of nutrition used and the clinical situation of the patient. Interpret these results in the light of an assessment of the acute phase response to determine if the trend of results is likely to be beneficial.
8. Use a biochemical indicator of the efficacy of antioxidant systems, such as malondialdehyde as a marker of oxidative damage. Although not yet in widespread use, such tests may prove helpful after more thorough evaluation.
9. Since all trace elements are potentially toxic if given in excessive amounts, special care must be used when providing such elements intravenously, especially if there is liver or kidney dysfunction. There has been substantial concern regarding excess intravenous provision of manganese leading to deposition in extrapyramidal tracts in the brain, causing a Parkinson's disease condition.
10. Most hospitals will have developed protocols for assessment and monitoring of patients who require nutritional support either intravenously or enterally. Laboratory staff should be aware of these protocols and should assist in their development to ensure that both the value and the limitations of particular tests in specific patients are fully understood.

CASE STUDIES*

Vitamin A

A 14-year-old from the United States with a history of recurrent cough and three episodes of pneumonia during the past 3 years was hospitalized for evaluation of short stature and delayed puberty. Other symptoms included large, bulky stools; dry, rough skin; and difficulty with vision at night. Examination of his stool showed large amounts of fat, and a sweat chloride analysis was consistent with a diagnosis of cystic fibrosis of the pancreas. A serum vitamin A (retinol) analysis showed a concentration of 11 μg/dL (0.4 μmol/L) (normal, 26-72 μg/dL). This patient illustrates the following points: (1) vitamin A deficiency may occur in developed countries; (2) vitamin A deficiency commonly occurs in conditions associated with fat malabsorption, and such individuals should receive routine vitamin A supplements; and (3) deficiency of vitamin A leads not only to difficulties in dark adaptation, but also to abnormalities in pulmonary epithelium and skin and may be associated with an increased incidence of pulmonary infections.

Vitamin E

A 47-year-old woman with progressive obstructive jaundice caused by sclerosing cholangitis for the past 10 years developed a limp. Physical examination indicated weakness in both lower limbs and loss of deep tendon reflexes in both upper and lower limbs. Despite daily supplements of vitamin E, blood levels were too low to be accurately measured. Subsequent treatment with large doses (5 to 10 times the RDA) did not increase blood levels of vitamin E. However, supplements of tocopherol, as a succinate ester preparation, increased blood levels of vitamin E and improved muscle strength. This patient's clinical picture demonstrates the following points: (1) patients with chronic biliary tract disease are at risk for vitamin E deficiency; (2) clinical manifestations of vitamin E deficiency are primarily neurological and manifest as weakness; (3) if treated early, these manifestations are reversible but may require several months or 1 to 2 years to develop; and (4) standard preparations of vitamin E are poorly absorbed in patients with chronic deficiency of intestinal bile acids, whereas the highly solubilized vitamin E succinyl ester is more readily absorbed in the absence of bile salts.

Vitamin K

A 23-year-old was hospitalized because of a 3-week history of progressive jaundice and chalk-colored stools. During subsequent tests to determine the cause of complete obstruction of bile flow, blood in the urine and feces was noted. A prolonged prothrombin time of 21 seconds was demonstrated. Vitamin K (1 mg) administered intramuscularly resulted in a normal prothrombin time of 12 seconds within 2 hours of the injection and in the resolution of the blood in urine and feces. This patient's history demonstrates the following: (1) the depletion time of vitamin K is relatively short compared with that of other fat-soluble vitamins; (2) bile salts are required for the absorption of vitamin K; and (3) response to systemic administration of vitamin K is prompt.

Thiamine

Study 1

A 44-year-old man was having difficulty concentrating. His employer referred him for evaluation because of observed weight loss, poor memory, a recent reduction in job performance, and mild generalized muscle weakness. History indicated a long-term problem with excessive alcohol intake. Serum electrolytes showed evidence of an organic aciduria that was subsequently found to be caused by lactic acid. Plasma thiamine levels were undetectable, and erythrocyte thiamine pyrophosphate levels were 25% of normal. Treatment with systemic thiamine for 3 days, followed by daily oral thiamine, was associated with a gradual improve-

*The authors gratefully acknowledge the original contributions of Donald B. McCormick, Harry L. Green, George G. Klee, and David B. Milne, on which portions of this appendix are based.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

ment in central nervous system function during the next 5 weeks. This patient illustrates thiamine (vitamin B_1) deficiency from chronic alcoholism—one of the most common vitamin deficiency disorders of developed countries. If diagnosed early, most symptoms resolve with thiamine supplementation.

Study 2

A 55-year-old man was admitted to the ICU after a serious road accident with intraabdominal trauma requiring major surgery. He was commenced on TPN but had a stormy postoperative course with infection and persistent ileus. Two weeks later he developed progressive dyspnea, hypotension, and clouding of consciousness. Arterial blood gases showed pH.7.10, bicarbonate 6 mmol/L, PCO_2 10.5 Kpa (60 mm Hg). His TPN had not contained any thiamine because of a lack of availability. High dose intravenous thiamine was given and his condition improved rapidly within 6 hours and the acidosis corrected over 48 hours. This case illustrates a rare but very serious form of beriberi (Shoshin beriberi), which is characterized by rapidly developing heart failure with severe metabolic acidosis. It is life-threatening and is most likely to occur where there is hypercatabolism with markedly increased carbohydrate metabolism along with inadequate thiamine supply. Diagnosis depends on clinical awareness and response to thiamine supplements; there is insufficient time for laboratory confirmation before thiamine must be given.

REFERENCE

Velez RJ, Myers B, Guber MS. Severe acute metabolic acidosis (acute beriberi): an avoidable complication of total parenteral nutrition. JPEN 1985;9:216-9.

RIBOFLAVIN

A 14-day-old exclusively breast-fed premature infant showed persistent jaundice and was treated for 30 minutes every 4 hours by exposure to standard blue fluorescent lights for hyperbilirubinemia. During the next 2 weeks, he showed a progressive decrease in bilirubin but began to feed poorly and developed a rash around his mouth and nose. Plasma riboflavin levels and urinary excretion of riboflavin were undetectable. Treatment with multiple vitamin drops containing the RDA of riboflavin resulted in a prompt resolution of feeding problems and skin changes. This case emphasizes that the breast milk content of riboflavin, although adequate for normal infants, may not meet the needs of infants requiring light treatment for hyperbilirubinemia. In this situation, light degrades riboflavin as well as activating it. Hence the dietary need is increased for riboflavin during treatment. The content of human milk riboflavin varies considerably among mothers.

VITAMIN B_6

An infant who was born 6 weeks prematurely developed generalized tonic seizures at 18 days of life. The pregnancy had been complicated by the discovery of active pulmonary tuberculosis in the mother 2 months before delivery, at which time treatment with streptomycin and isonicotinic acid hydrazide (INH) was initiated. The infant had been exclusively breast-fed. Blood for pyridoxine measurement was obtained, and 2 mg of pyridoxine was given intravenously. Seizure activity in the infant ceased during the next 40 minutes and subsequent results of blood pyridoxine showed the plasma pyridoxal phosphate to be undetectable, as was the content of plasma pyridoxine and pyridoxal. Supplemental pyridoxine treatment for the mother was initiated, and no subsequent seizure activity occurred in the infant. This case emphasizes the following points: (1) INH interferes with the metabolism of vitamin B_6, and patients should receive B_6 supplements during treatment with this drug because it is also secreted in breast milk; (2) breast milk vitamin B_6 content is a function of vitamin B_6 nutriture; and (3) in the neonate, B_6 deficiency is manifested by seizures.

NIACIN

A 31-year-old man was treated with niacin at a dose of 6 g daily for an elevated blood triglyceride level of 6.8 mmol/L (reference interval, 0.9 to 2.0 mmol/L). Blood triglyceride levels declined to 2.1 mmol/L during the subsequent 3 months. After 6 months of treatment, he complained of fatigue and vague abdominal pain; his fasting blood glucose level was 14.6 mmol/L (normal, 3.9 to 5.0 mmol/L), and his insulin level was 210 U/mL. The niacin administration was discontinued for 48 hours and then reinitiated at a dosage of 4 g daily with subsequent improvement in symptoms and in blood glucose and insulin levels. This case emphasizes the following points: (1) pharmacological doses of niacin may be useful in the management of certain types of hyperlipidemia; (2) a toxic effect of niacin is insulin resistance; and (3) the insulin resistance is dose dependent, and administration of the drug may be continued at a lower dose.

BIOTIN

Following superior mesenteric artery thrombosis, a 28-year-old woman had been receiving home TPN for 3 years and was maintaining weight and good health. She then started to develop mucocutaneous rashes in the mouth and perineal region. A clinical diagnosis of zinc deficiency was made, but despite increased zinc provision, she developed progressive alopecia, myalgia, depression, anergy, and vomiting. Results of all routinely measured trace elements and vitamins were normal. Review of her supplements showed a lack of biotin. Plasma biotin was measured microbiologically, and the result was below the 10th centile. The TPN was supplemented with a vitamin preparation containing biotin, and within 3 weeks the anergy, arthralgia, and myalgia had settled; within one further month, the rashes and alopecia had resolved. Subsequent investigations showed elevated urinary organic acids before supplementation—especially lactic, 3OH-butyric, propionic, and 3OH valeric acids, typical of biotin deficiency. This case demonstrates: (1) the

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

importance of careful review of intake and ensuring all essential nutrients are supplied to patients requiring TPN; (2) the value of measuring metabolic end products, which may be more available than measurements of the vitamin; and (3) when in doubt, a therapeutic trial of supplements may be the best way to demonstrate a deficiency.

REFERENCE

Pantothenic Acid

Because pantothenate deficiency is unlikely to occur except in experimental situations, and pantothenate toxicity has not been described in the literature, we have not included a case history for pantothenate.

Folic Acid

A 26-year-old female presented with aches and pains, particularly in her legs, tiredness, and weight loss. She had a 6-month-old daughter and had been anemic throughout pregnancy. She was currently taking oral iron supplements, but there was no other significant history. Dietary intake was satisfactory. Laboratory investigation showed hemoglobin 10.4 g/dL, hematocrit 32.9%, MCV 76.4, ferritin 5 μg/L (reference interval 15-165), folate 0.6 μg/L (reference interval 1.5 to 10 μg/L), serum calcium 1.82 mmol/L, albumin 44 g/L, and alkaline phosphatase 235 U/L (reference interval 30 to 130 U/L). This case illustrates multiple deficiencies of iron, folate, and vitamin D resulting in anemia and osteomalacia. The likely diagnosis is celiac disease resulting in impaired absorption. Multiple trace element or vitamin deficiencies are common when there is either a generalized reduction in dietary intake or a failure in digestion or absorption. Laboratory tests are of great value in identifying the abnormalities, confirming the diagnosis, and monitoring the effectiveness of therapy.

Ascorbic Acid

An 18-year-old woman with rheumatoid arthritis who had been treated chronically with antiinflammatory medication was hospitalized because of generalized abdominal pain and abdominal tenderness with some distension. She had some blood in her last bowel movement. During the preceding 2 months, she had been intolerant of many foods, particularly vegetables and fruits, and had restricted her diet to milk, boiled eggs, bread, and cheese. In addition, during the preceding 2 weeks, she noted several bruises and small red spots (petechiae) on her lower legs; these had faded within the week but reappeared 2 days before admission. Her skin was also very dry and rough (despite treatment with a skin cream), with raised areas at the base of hairs. Although the joint pain from arthritis had improved over the last month, there was now new pain below the joints of both knees and her ribs were tender at the costochondral joints. The serum ascorbate level was 4.5 μmol/L (normal, 23-85 μmol/L). This case illustrates the following points: (1) individuals with chronic illness are at increased risk of vitamin deficiencies; (2) overt deficiency of ascorbate can occur relatively rapidly (within 1 month) of dietary restriction of ascorbate, if it is already marginally deficient; (3) the pain of arthritis differs from the pain associated with overt deficiency of ascorbate; and (4) although unusual, ascorbate deficiency may result in gastrointestinal bleeding.

Chromium

A 40-year-old woman who had been receiving TPN for 3½ years developed unexpected weight loss and peripheral neuropathy. An intravenous glucose tolerance test showed impaired glucose tolerance with borderline insulin response. Chromium concentration in whole blood was low at 0.55 ng/mL (reference interval 4.9 to 9.5 ng/mL) and in hair 154-175 ng/g (reference interval >500 ng/g). Administration of insulin nearly maintained euglycemia, but the glucose tolerance test remained abnormal. Insulin was stopped and 250 μg chromium per day was added to the TPN for 2 weeks. The intravenous glucose tolerance normalized, and insulin was no longer required. Over the next 5 months, nerve conduction and well-being returned to normal, and the patient was maintained on an intravenous chromium intake of 20 μg per day. This case illustrates the following points: (1) any patient who develops a metabolic abnormality, having been stable on long-term TPN, should be assessed for possible micronutrient deficiency; (2) chromium deficiency is very rare, probably because of contamination in TPN solutions; and (3) patients developing glucose intolerance should be assessed for possible chromium deficiency. Laboratory confirmation is difficult, and a trial of chromium supplements is probably the easiest way to confirm chromium deficiency.

Copper

A 36-year-old female underwent a subtotal small bowel resection and after anastomosis was left with short bowel syndrome, requiring intravenous feeding. After 6 months she developed cholestasis, hyperbilirubinemia, and raised liver enzymes. It was decided to omit the daily copper supplements in view of concerns that continued IV copper administration in the presence of cholestasis would cause hepatic copper overload. It was expected that sufficient copper could be absorbed from her limited oral diet through her remaining small bowel. Fifteen months later, the patient required transfusion for treatment of symptomatic anemia. Her white blood cell (WBC) and platelet counts steadily declined

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

and she required further red cell transfusions. The serum copper was found to be 25 μg/dL (reference interval 70 to 155 μg/dL), and serum ceruloplasmin was 7.1 mg/dL (reference interval 15 to 60 mg/dL) on day 133 after the commencement of IVN. A standard trace element supplement containing 1 mg copper was added daily to the IVN fluids. Serum copper levels rose and the neutropenia and thrombocytopenia improved rapidly. Only one more red cell transfusion was required for the next 124 days. When the patient's serum copper rose to 186 μg/dL on day 174, copper supplementation was discontinued. Over the next 3 months, serum copper values rapidly declined to 10 μg/dL, and the neutropenia, thrombocytopenia, and anemia recurred, requiring further red cell transfusions. Reinstatement of IV copper supplementation reversed these changes once more. This case illustrates: (1) during provision of IV copper, the risk of hepatic copper accumulation in the presence of cholestasis has to be balanced against the risk of copper deficiency; (2) there is a need for regular monitoring of serum copper concentration to detect either impending toxicity or deficiency during prolonged IVN; (3) the considerable length of time that it took for the hematological changes to be apparent indicates that some residual copper absorption may have occurred and that copper tissue stores, possibly from the liver, were being mobilized; and (4) the low platelet count along with the neutropenia and iron-resistant anemia is unusual.

MANGANESE

A 62-year-old man had been receiving TPN for 31 months following massive small bowel resection. Trace element provision had included 2.2 mg (40 μmol) manganese per day, an amount commonly used at the time. He was admitted as a result of developing worsening gait disturbance over the past 16 months. His whole-blood manganese had been 3.0 to 5.6 μg/dL (reference interval 0.4 to 2.0 μg/dL), but serum and plasma manganese had never been above the reference interval. He was diagnosed as having parkinsonism, with dysarthria, mild rigidity, masked face, and halting gait. A magnetic resonance scan showed high signal intensity on T1-weighted images in the basal ganglia and pons, consistent with manganese deposition. Trace element supplements were discontinued, and 15 weeks later whole-blood manganese had fallen to 0.5 μg/dL, with reduction in the high intensity images. Symptoms had also significantly decreased. This case illustrates: (1) high intravenous supply of manganese can cause toxic symptoms; (2) whole-blood manganese is a better marker of manganese status than plasma or serum manganese; (3) an MRI can help identify tissue deposition of manganese due to excess provision; and (4) recommendations for intravenous manganese supply have been greatly reduced since the demonstration of cases of toxicity during TPN.

SELENIUM

Study 1

A 21-month-old girl with microvillus atrophy causing severe malabsorption had been maintained on total parenteral nutrition at home from the age of 4 months. However, there was no selenium in the additives used and her oral intake was minimal. She began to have difficulty walking and crawling, and her leg and feet muscles were tender but there was no wasting. Routine hematological and biochemical investigations were normal, but plasma selenium was very low at <0.5 μmol/L, 0.4 μg/dL (reference interval 0.8 to 1.6 μmol/L, 6.3 to 12.6 μg/dL). RBC glutathione peroxidase was undetectable and plasma glutathione peroxidase was 6 U/L (reference interval 90 to 350 U/L). An electromyogram (EMG) suggested a myopathic process with increased polyphasia and reduced amplitude potentials. A needle biopsy showed an increase in the amount of connective tissue between muscle fibers, and type 1 fibers were normal for her age but type 2 fibers were atrophied. The muscle selenium concentration was 0.23 μg/g dry weight (adult reference interval 0.45 to 1.05 μg/g dry weight). Intravenous sodium selenite equivalent to 15 μg Se/day was provided, and within 3 days the muscle pain had lessened and within 6 weeks the patient was walking normally. After 3 months plasma selenium was 0.53 μmol/L (4.2 μg/dL), and RBC glutathione peroxidase was normal.

Study 2

A 24-year-old man who had been receiving TPN for 6 years for chronic intestinal pseudo-obstruction died suddenly from cardiomyopathy and ventricular fibrillation. Micronutrient supplements did not include selenium. Post-mortem analysis revealed myocytolysis and replacement fibrosis in the heart, very low concentrations of selenium, and low activity of glutathione peroxide in blood, heart, liver, and skeletal muscle.

These cases illustrate the following: (1) selenium should be included in the additives used in intravenous feeding; (2) the dosage administered has to be sufficient to prevent deficiency but not so high as to risk toxicity; (3) the clinical presentation of selenium deficiency may be with skeletal or cardiac myopathy, which may be very severe; and (4) regular

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

monitoring of plasma selenium and red blood cell glutathione peroxidase is advisable when patients are receiving selenium supplements.

ZINC

A 58-year-old male underwent a total gastrectomy for gastric carcinoma. He had multiple postoperative complications and intravenous feeding was started. Despite further problems—including sepsis, cholestatic jaundice, and cardiac arrhythmias—he improved by the end of the fourth week, with reversal of catabolism. Urinary zinc losses were very high, reaching a peak during the third week of 22.6 mg/24 hours (reference interval 0.5 ± 0.3 mg/24 h.) The calorie intake was built up to more than 5000 kcal/day and a weight gain of 10 kg was noted over 3 weeks. The urine zinc excretion fell to near the reference interval, but the plasma zinc continued to decline and at 10 weeks was very low at 8 μg/dL (reference interval 80 to 120 μg/dL). The patient's condition deteriorated and he became mentally confused and developed a moist scrotal rash, swelling of the lips, and perioral crusting. The skin changes became severe and loss of scalp hair was noted. Intravenous zinc supplementation was commenced at 80 mg zinc sulfate daily (200 μg Zn/day), reducing to 40 mg zinc sulfate/day after 5 days. Within 48 hours, the rash and mental condition improved although loss of scalp hair continued. Ten days after starting zinc treatment, both the scrotal and facial skin changes had cleared but the alopecia was significant. His mental state was normal and his overall condition excellent.

This case illustrates the following points: (1) zinc losses during severe catabolic illness after surgery can be considerable. In this case these were the substantial losses of zinc in urine with unknown additional amounts in drain fluids and feces; (2) the input of zinc from the crystalline amino acid infusions and other IV nutrients and additives was insufficient to meet these increased losses; (3) signs and symptoms of acute zinc deficiency were first seen after body weight gain was restored and the tissue regrowth required extra zinc for cell division and protein synthesis; (4) although many factors can cause a nonspecific fall in plasma zinc, demonstration of a very low concentration (below 50% of the lower limit of the reference interval) is strongly suggestive of zinc deficiency; and (5) zinc (and other micronutrients) should be routinely added to IVN regimens and regular monitoring of plasma zinc carried out to ensure that dosage is adequate.

APPENDIX 31

Hemoglobin, Iron, and Bilirubin

Trefor Higgins, M.Sc., Ernest Beutler, M.D., and Basil T. Doumas, Ph.D.

Included in this section are the following methods:

1. Method 31-1: Determination of Total Bilirubin (Reference Method based on the Jendrassik and Gróf Principle) and Direct-Reacting Bilirubin in Serum.
2. Method 31-2: Determination of Bilirubin in Infants by Direct Spectrophotometry.

In addition, conjugated bilirubin—defined as the sum of bilirubin monoglucuronide and diglucuronide—can be measured by HPLC, by a commercially available clinical analyzer (Vitros), and enzymatically by bilirubin oxidase.[5] Methods for the determination of bilirubin in urine and feces can be found in the third edition of this textbook.[10]

METHOD 31-1: DETERMINATION OF TOTAL BILIRUBIN (REFERENCE METHOD[3] BASED ON THE JENDRASSIK AND GRÓF PRINCIPLE) AND DIRECT-REACTING BILIRUBIN IN SERUM

Principle

Total bilirubin in serum or plasma is measured by adding caffeine reagent (accelerator) to the specimen, followed by the addition of diazotized sulfanilic acid. During the incubation period, sugar-conjugated, unconjugated, and delta bilirubin react with the diazo reagent to produce azobilirubin (azopigment). Ten minutes after the addition of diazotized sulfanilic acid, solutions of ascorbic acid and alkaline tartrate are added to the reaction mixture. The absorbance of the resulting blue-green alkaline azobilirubin solution is measured at 598 nm.

To measure direct bilirubin, the serum or plasma is acidified with dilute hydrochloric acid and then mixed with diazotized sulfanilic acid to produce azobilirubin. Only the sugar conjugated and δ-bilirubin react with the diazo reagent in the absence of the accelerator caffeine-benzoate. The reaction is stopped by the addition of an ascorbic acid solution, which destroys excess diazo reagent. Then an alkaline tartrate solution is added to the reaction mixture, followed by the addition of an aliquot of the caffeine reagent. The latter shifts the absorbance peak of azobilirubin from 585 to 598 nm, at which the absorbance is measured. The tartrate reagent provides an alkaline pH to produce the blue color of azobilirubin.

Specimen Collection and Storage

Serum or plasma may be used as the specimen. A morning specimen from a fasting subject is preferred to avoid lipemia. Excessive hemolysis (serum hemoglobin >300 mg/dL) should be avoided because it may falsely lower the bilirubin value. Hemoglobin interference is far more serious with diazo methods for direct bilirubin.[4] Because both conjugated and unconjugated bilirubin are photo-oxidized when exposed to white or ultraviolet light, specimens should be protected from direct exposure to either artificial light or sunlight as soon as they are drawn. The sensitivity to light is temperature-dependent; for optimal stability, storage of specimens in the dark and at low temperatures is essential. When specimens are stored in the refrigerator, stability is maintained for 3 days. Specimens are stable for 6 to 12 months when stored frozen at −70 °C in the dark.

Reagents (for Both Total and Direct Bilirubin)

1. Caffeine-benzoate reagent. Dissolve 56 g anhydrous sodium acetate, 56 g sodium benzoate, 1 g disodium ethylenediaminetetraacetic acid (EDTA), and 37 g caffeine in ~700 mL of water. Dilute to 1 L. This reagent is stable for at least 6 months at room temperature.
2. Hydrochloric acid, 0.05 mol/L.
3. Sulfanilic acid, 5 g/L. Add 5 g of sulfanilic acid to 700 mL of water. Add 15 mL of concentrated hydrochloric acid. Dilute to 1 L. Store at room temperature.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

4. Sodium nitrite, 5 g/L. Dissolve 0.5 g of sodium nitrite in 70 mL of water and dilute to 100 mL. Store at 4 °C. Prepare fresh every 2 weeks.
5. Diazotized sulfanilic acid. Mix 20 mL of the sulfanilic acid solution with 0.5 mL of the sodium nitrite solution. Prepare fresh daily and store at 4 °C.
6. Ascorbic acid solution, 40 g/L. Dissolve 200 mg of ascorbic acid in 5 mL of water. Prepare fresh daily and store at 4 °C.
7. Alkaline tartrate solution. Dissolve 75 g of sodium hydroxide and 320 g of sodium potassium tartrate tetrahydrate in 700 mL of water. After the solution has cooled, dilute to 1 L and filter if turbid. This reagent is stable for at least 6 months at room temperature.
8. Tris buffer (0.1 mol/L pH 7.3). Dissolve 12.1 g of tris(hydroxymethyl)aminomethane in approximately 800 mL of water. Adjust to pH 7.3 ± 0.05 with hydrochloric acid and dilute to 1 L. Store at 4 °C. Solution is stable for at least 6 months.
9. Bovine serum albumin (BSA) diluent (40 g/L). Dissolve 10.0 g of BSA in 200 mL of tris buffer. If necessary, adjust the pH of the solution to 7.35 ± 0.05 before diluting to 250 mL with tris buffer. This solution is used in preparing the stock and working bilirubin standard solutions. Store at 4 °C for 2 to 3 days, or for longer storage, at −20 °C in convenient aliquots.
10. Sodium carbonate (0.1 mol/L). Dissolve 1.06 g of anhydrous Na_2CO_3 in 100 mL of water.

Note: Use reagent-grade water for the preparation of all reagents.

Calibrators and Calibration

Only unconjugated bilirubin of acceptable purity should be used for establishing calibration curves. Such preparations include the bilirubin Standard Reference Material 916a from the National Institute of Standards and Technology (Gaithersburg, Md.) or its equivalent. Calibrators made with bilirubin from other sources must be traceable to those made with the SRM 916a. The molar absorptivity values (ε) of the SRM 916a bilirubin and of its neutral and alkaline azopigments were established by interlaboratory studies conducted in European and U.S. laboratories on two occasions.[2,8] The results from these studies are shown in Table A31-1. The ε values of bilirubin in the caffeine reagent at 432 nm and 457 nm were measured because it has been shown[11] that in this reagent the spectra of bilirubin are not affected by commonly used protein matrices, such as human serum albumin (HSA), BSA, or human serum.[6] An acceptable diluent for the stock calibrator of unconjugated bilirubin is a BSA Cohn Fraction V, 40 g/L solution. The bilirubin stock calibrator, prepared as described below, is suitable for the reference method, and methods using caffeine or dyphylline as accelerators. It is not suitable for measuring bilirubin by direct spectrophotometry and may not be suitable for diazo methods that use other accelerators.

1. Stock calibrator (20 mg/dL). Weigh about 20 mg of bilirubin SRM 916a to the nearest 0.01 mg in a plastic weighing dish (do not use glassine paper) and transfer it to the bottom of a 100-mL volumetric flask with the aid of 1.0 mL of dimethylsulfoxide. Swirl the contents of the flask until all of the bilirubin is finely dispersed. Wash the plastic dish and the neck of the flask with 2.0 mL of sodium carbonate solution (reagent No. 10). Swirl gently until a crystal-clear, red-orange solution is obtained. Dilute the solution to 100 mL with the BSA diluent (reagent No. 9). Because bilirubin is light sensitive, the flask should be wrapped with aluminum foil to protect the solution from light as much as possible. The stability of the stock calibrator depends on the storage temperature. Deterioration is about 1.5% per month at −20 °C, but is stable for at least 6 months at −70 °C.

Note: Bilirubin SRM 916a contains 1.7 percent (by weight) impurities. Correct the amount of bilirubin weighed by multiplying by 0.983.

   a. Check the acceptability of the bilirubin stock calibrator by centrifuging 5 to 7 mL of the solution at 1500 × *g* for 10 minutes and inspecting the test tube; if there is any orange sediment on the wall or the bottom of the test tube, the solution is unacceptable. Prepare it again making sure that all bilirubin is completely dissolved in the dimethylsulfoxide–sodium carbonate mixture before adding the BSA diluent.

TABLE A31-1 Corrected Molar Absorptivities (2001 vs. 1989) of NIST Bilirubin (SRM 916a) and of Its Neutral and Alkaline Azopigments

	Molar Absorptivity (ε) $L \cdot mol^{-1} \cdot cm^{-1}$			
	Caffeine Reagent		Reference Method	
Year Determined	432 nm*	457 nm*	530†	598†
1989	50,060 ± 580	48,890 ± 570	56,660 ± 1030	76,490 ± 610
2001	50,090 ± 850	49,240 ± 440	57,090 ± 730	76,640 ± 600

*Bilirubin.
†Azopigments.
Weighted mean ± standard deviation for six laboratories.
The molar absorptivity was calculated using the molecular weight of bilirubin (584.65).

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

b. Analyze the stock calibrator solution in triplicate by the procedure for total bilirubin described below; use Class A volumetric pipettes. Omit adding ascorbic acid before alkaline tartrate, because there is no hemoglobin in the sample. Also, analyze the BSA diluent in duplicate as a test and subtract its absorbance from that of the stock calibrator.
c. Calculate the molar absorptivity of the azopigment at 598 nm. Acceptable limits for the molar absorptivity are from 74,750 to 78,380; that is the mean value obtained in the two collaborative studies ± the average of 3 SDs (Table A31-1). For a detailed description of the preparation, analysis and acceptability, and storage of the stock calibrator, see reference 3.

2. Working calibrators. Dilute the stock calibrator with the BSA diluent (reagent No. 9) to prepare solutions containing 2.5, 5.0, and 10.0 mg/dL bilirubin. Dispense these and the 20.0 mg/dL bilirubin calibrator into cryogenic vials (Nalgene) filled to the top and store at −70 °C.
3. Calibration curve. Analyze the stock and the working calibrators, and the BSA diluent by the procedure for total bilirubin. Do not run sulfanilic acid blanks for the calibrators and the BSA diluent. Subtract the absorbance of the BSA diluent from the absorbance of each calibrator. Plot these corrected absorbance values against the corresponding bilirubin concentrations on linear graph paper; the relationship absorbance /concentration is linear to 25 mg/dL (425 umol/L).

Procedure: Total Bilirubin

(The following is a brief description of the reference procedure. Details on the procedure, number of standards, sample blank, and acceptability of results are given in reference 3.)

1. Use class A volumetric pipettes, or mechanical pipettors if the relative SD of repetitive delivery is near 0.3%. Flow-through cuvets instead of square cuvets may be used if carryover is eliminated by rinsing between samples. Work with the laboratory lights off and away from windows.
2. Analyze calibrators, serum specimens, controls, and sample blanks in duplicate. Analyze sample blanks first as a group followed by the specimens. Do not run sample blanks for the calibrators and the BSA diluent. Analyze the BSA diluent as a test and subtract its absorbance from those of the calibrators.
3. Test samples
   a. Add 4.0 mL of caffeine reagent (reagent No. 1) to a series of glass test tubes.
   b. Pipette 0.50 mL of each calibrator, sample, control, and BSA diluent, mix, and let stand for 10 minutes.
   c. Add 1.0 mL of freshly prepared diazotized sulfanilic acid reagent (reagent No. 5), mix immediately, and let stand for 10 minutes.
   d. Add 0.1 mL ascorbic acid solution and mix.
   e. Add 3.0 mL of alkaline tartrate, mix thoroughly, and let stand for 10 minutes before measuring the absorbance.
4. Sample blanks
   Use the same procedure as for the tests (steps 1-5 above), but substitute sulfanilic acid solution for diazo reagent in step 3.
5. Reagent blank
   Prepare a large volume of reagent blank by mixing 20 mL caffeine reagent, 2.5 mL water, 5 ml diazo reagent, and 15 mL alkaline tartrate. This solution is needed to check the photometric drift of the spectrophotometer.
6. Absorbance measurements
   a. Set the instrument at zero absorbance at 598 nm with the reagent blank.
   b. Measure the absorbance of all the sample blanks (A_1) and of the BSA diluent (analyzed as test), and then the absorbance of all tests (A_2).
   c. Correct the absorbance of the tests by subtracting that of the corresponding sample blanks (A_2–A_1).
   d. Correct the absorbance of the standards by subtracting that of the BSA diluent.
   e. Use the calibration curve or the regression equation of the calibrators to determine the concentration of total bilirubin in each unknown.

Comments

1. In our opinion, the acceptable lower and upper limits of the molar absorptivity (ε) value of the stock bilirubin calibrator should be the 76,560 (average value from the two studies) ± 1815(3 SD) (i.e., from 74,750 to 78,380).
2. The volumes of sample and reagents may be scaled down by a factor of 2 without an adverse effect on the precision of the method.
3. The large excess of sulfanilic acid (the molar ratio of sulfanilic acid to sodium nitrite is 16:1) is necessary for obtaining a rapid rate in the second stage of the coupling reaction.[6] When the molar ratio is decreased to 3:1 (1 g of sulfanilic acid per liter), the molar absorptivity of the azobilirubin at 598 nm is about 4% lower, probably because the coupling reaction does not go to completion.[12]

Direct Bilirubin (Preferred Method)

Keeping unconjugated bilirubin from reacting as direct requires that serum be incubated in 0.05 mol/L HCl for at least 5 minutes before adding diazo reagent. This preincubation decreases somewhat the reactivity of direct-reacting bilirubin fractions, but this is a far less serious drawback than measuring unconjugated bilirubin as direct. The following is a procedure that combines the most desirable features of several methods.[1]

1. Dilute 0.25 mL of sample with 1.0 mL of 0.05 mol/L HCl and let stand for 5 minutes (test). Add 0.5 mL diazo reagent (reagent No. 5) and incubate for 10 minutes at room temperature.
2. Add 0.1 mL ascorbic acid solution (reagent No. 6) followed by 1.5 mL alkaline tartrate and 2.0 mL caffeine reagent.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

3. Prepare a sample blank exactly as the test, except for substituting sulfanilic acid for diazo reagent.
4. Measure the absorbance of test and blank against water at 598 nm and subtract the absorbance of the blank from that of the test.
5. Calculate the concentration of direct bilirubin in the sample against a standard of unconjugated bilirubin analyzed by the procedure for total bilirubin (i.e., dilute the sample with caffeine reagent instead of HCl and add HCl after the alkaline tartrate).

Comments

1. Dilution of serum with dilute HCl and allowing it to stand for 5 minutes before adding the diazo reagent keeps the unconjugated bilirubin from reacting as direct.
2. The historical 1-minute reaction underestimates direct bilirubin, and even after a 10-minute coupling time, the reaction is not complete.
3. Ascorbic acid is added to destroy excess diazo reagent, which would react with unconjugated bilirubin when alkaline tartrate is added.
4. The caffeine reagent suppresses the absorptivity of the azopigment at 598 nm by about 12%.[7] Omission of the caffeine reagent in this assay has been responsible for the paradox of sometimes having direct bilirubin values exceeding those of total bilirubin.
5. Interference by hemoglobin is far stronger than in the method for total bilirubin.[4] The negative bias is due to oxidation of conjugated bilirubin to the diazo negative biliverdin and to the destruction of the azopigment by H_2O_2 produced by the conversion of hemoglobin to methemoglobin at the low pH of the reaction medium; the negative bias is substantially reduced by addition of potassium iodide to the serum diluent (HCl).[9] Although direct bilirubin values are artifactually lowered even at hemoglobin concentrations of 50 to 100 mg/dL, it is doubtful that this negative bias would ever cause a misdiagnosis of cholestasis.
6. Under the conditions of this assay, the contribution of unconjugated bilirubin is negligible; a 20 mg/dL (340 µmol/L) solution of unconjugated bilirubin in human serum or HSA analyzed by this procedure will yield a direct bilirubin value between 0.2 and 0.3 mg/dL.

Reference Intervals

In adults and infants older than 1 month, the normal reference interval for total serum bilirubin is 0.2 to 1.2 mg/dL (3.4 to 20.5 µmol/L); conjugated bilirubin is 0 to 0.2 mg/dL (0 to 3.4 µmol/L). Reference intervals for serum total bilirubin of newborns are summarized below:

	Premature		Full-Term Newborn	
Age	**mg/dL**	**µmol/dL**	**mg/dL**	**µmol/dL**
Up to 24 hr	1.0-8.0	17-137	2.0-6.0	34-103
Up to 48 hr	6.0-12.0	103-205	6.0-10.0	103-171
Days 3-5	10.0-14.0	171-239	4.0-8.0	68-137

METHOD 31-2: DETERMINATION OF BILIRUBIN IN INFANTS BY DIRECT SPECTROPHOTOMETRY

Principle

Bilirubin in human serum exhibits an absorption maximum near 460 nm. If it were the only absorbing species, bilirubin could be quantified in serum by simply measuring the absorbance near 460 nm. Because carotenes and other pigments are virtually absent in the newborn's blood, hemoglobin is the only pigment in serum that interferes with the bilirubin measurement; this interference is eliminated by analysis of a two-component system. The measurement involves making absorbance measurements at two wavelengths and determining the absorptivities (molar absorptivities or absorbance of 1 mg/dL) of bilirubin and hemoglobin at the selected wavelengths. The first wavelength is chosen near the absorption maximum of bilirubin; the second near an absorption minimum. The concentration of bilirubin is calculated by solving a system of two simultaneous equations having two unknowns. Calculations become simple if the two wavelengths are isosbestic for hemoglobin; such wavelengths are 454 nm and 540 nm.

Note 1: The measurement is based on two assumptions: (1) Unconjugated bilirubin is virtually the only bilirubin present in serum of the healthy newborn; (2) hemoglobin is the only other absorbing species in serum.

Note 2: Bilirubin solutions in human serum, HSA, or BSA exhibit a single absorption spectrum with maxima at 432 nm and 457 nm when diluted with the caffeine reagent. Direct spectrophotometry of neonatal sera diluted with caffeine reagent provided results in very good agreement with those obtained by the reference method.[11]

Note 3: Turbidity (lipemia) will cause a negative bias if the secondary wavelength is shorter than the primary, and a positive bias if it is longer. This is because light scattering (and hence absorbance) varies inversely with the wavelength.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

Specimen Collection

Draw a capillary blood specimen from the heel or fingertip. Avoid hemolysis.

Reagent

Phosphate buffer, 0.1 mol/L, pH 7.4. Weigh out 7.65 g of $Na_2HPO_4 \cdot 7\ H_2O$ and 1.74 g of KH_2PO_4 (anhydrous). Dissolve in water and dilute 1 L in a volumetric flask. Check the pH with a pH meter and adjust if necessary. Store refrigerated.

Procedure

1. With a micropipette, add 20 µL of serum to a microcuvet (10-mm light path) containing 1 mL of phosphate buffer. Rinse the pipette several times with the buffer, but avoid bubbles.
2. Add 1 mL of phosphate buffer to another microcuvet and, using this as a blank, set the spectrophotometer at zero absorbance; read the absorbance of the diluted serum at 454 and 540 nm. To obtain sufficiently accurate absorbance readings required by this method, a spectrophotometer with a bandpass of less than 8 nm should be used.

Calculations

Prepare a bilirubin stock calibrator (20 mg/dL) as described in the procedure for total bilirubin, but substitute human serum for BSA. The serum pool should be optically clear and nonhemolyzed, and have a low bilirubin content (<0.3 mg/dL).

Dilute the stock calibrator with the serum pool to obtain solutions containing 5.0 and 10.0 mg/dL bilirubin.

Pipette in duplicate 100 µL of each bilirubin calibrator into test tubes. Add 5.0 mL of phosphate buffer, mix, and read the absorbance at 454 nm and 540 nm against the buffer. Subtract the absorbance at 540 nm from that at 454 nm and divide the difference (DA) by the bilirubin concentration (divide the bilirubin concentration of each calibrator by 51, the dilution factor, to obtain the actual concentration) of the appropriate calibrator to obtain the factor (i.e., absorbance per milligram of bilirubin per deciliter). The factors obtained from the three calibrators should be almost identical. For the SRM 916a in human serum, the average ΔA value should be $0.84 \cdot mg^{-1} \cdot dL$; its reciprocal is 1.19 mg/dL. The calculating equation for unknowns is therefore

$$\text{Bilirubin, mg/dL} = (A_{454} - A_{540}) \times 1.19 \times 51$$

where 51 is the dilution factor. Alternatively, a calibration curve as described above may be prepared using ΔA_2 values of the three calibrators.

Comment

In our opinion, the calibrator for direct spectrophotometry described above should be suitable for calibrating all methods for total bilirubin, because its matrix is almost identical to blood specimens drawn from human subjects. Furthermore, the use of materials consisting of unconjugated bilirubin in human serum by providers of proficiency testing would check the accuracy of all bilirubin methods, because it would eliminate matrix effects.

APPENDIX 32

Porphyrins and Disorders of Porphyrin Metabolism

Allan C. Deacon, B.Sc., Ph.D., Dip.C.B., F.R.C.Path., Sharon D. Whatley, Ph.D., and George H. Elder, M.D.

ANALYTICAL METHODS

The analytical methods used in conjunction with porphyrias are described here fully. Brief descriptions are available in the printed version of this textbook.

Methods for Metabolites

The metabolite methods include ALA, PBG, and urinary, fecal, plasma, and blood porphyrins.

Specimen Collection and Stability

All samples must be protected from light; urinary porphyrin concentrations can decrease by up to 50% if kept in the light for 24 hours. Urinary porphyrins and PBG are best analyzed in fresh, random (10 to 20 mL) samples collected without preservative. Very dilute urine (creatinine less than 4 mmol/L) is unsuitable for analysis.

With the exception of congenital erythropoietic porphyria (CEP), urine is often of normal color in the nonacute porphyrias. During the acute attack, urine may be a reddish color due to the nonenzymatic condensation of PBG to uroporphyrins and other pigments.

Twenty-four-hour collections offer little advantage, delay diagnosis, and increase the risk of losses during the collection period. PBG and porphyrins are stable in urine in the dark at 4 °C for up to 48 hours and for at least a month at –20 °C. Specimens for ALA estimation should be promptly refrigerated. Urine specimens can be stored at 4 °C in the dark for at least 2 weeks without significant loss of ALA,[124*] and frozen specimens are stable for weeks.[12] Whereas PBG is more stable around pH 8 to 9, ALA is more stable around pH 3 to 4, although more acidic environments notably reduce ALA stability.

About 5 to 10 g wet weight of feces is adequate for porphyrin measurements. Diagnostically important changes in concentration are unlikely to occur within 36 hours at room temperature and samples are stable for many months at –20 °C.

Blood, anticoagulated with EDTA, shows no loss of protoporphyrin for up to 8 days at room temperature and for at least 8 weeks at 4 °C in the dark.

Available Methods for Porphyrin Precursors

PBG and ALA are water soluble and concentrate in the urine, and are therefore measured almost exclusively in the urine in the clinical laboratory. PBG is in general the more important of the precursors, whereas ALA is used more as a supplemental test.

Porphobilinogen

Most methods for PBG are based on the reaction of Ehrlich's reagent (4-dimethylaminobenzaldehyde in acidic solution) with the α-methene carbon of the pyrrole ring to form a colored product variously described as "rose-red" or "magenta," which has a characteristic absorption spectrum with a peak at 553 nm and a shoulder at 540 nm. Porphyrins do not contain any α-methene hydrogens and so do not react. Some other substances in urine either react with the reagent to give red products, notably urobilinogen; inhibit the reaction; or are pigmented themselves and so mask the red chromogen.[25,159] All need to be removed. This is best achieved by ion exchange chromatography (first described by Mauzerall and Granick[97]), but methods for accurate quantification of PBG based on this procedure are time consuming. More sensitive methods based on HPLC[75] and tandem-MS[49] are available.

Qualitative screening tests in which urine is reacted directly with Ehrlich's reagent and assessed visually for the formation of the red chromogen (e.g., the Watson-Schwartz[149] and Hoesch[86] tests), are convenient but have been criticized for poor detection limits and interferences, even when solvent extraction has been used to separate the PBG-Ehrlich compound from the urobilinogen-Ehrlich complex.[16,17,27,134]

The Mauzerall and Granick method has been modified in attempts to produce an alternative that is acceptable for screening purposes. Buttery et al[18,19] avoided the use of columns by employing batchwise treatment with resin, and visually compared the final color with that of a surrogate calibrator. Blake et al[8] eliminated the centrifugation steps by using resin-filled syringes with detachable filters and compared the final color with a range of artificial calibrators. These modifications reduced the time taken to perform the test to 10 minutes and produced a semiquantitative result. A commercial kit based on Blake's method is available (Trace PBG Kit; Alpha Laboratories, Eastleigh, Hampshire, UK) and appears to be more analytically sensitive and specific for initial screening than qualitative, solvent extraction procedures.[32] A recent innovation uses resin-filled nylon sacs.[61]

If a qualitative screening test is used, it is essential to include appropriate controls and confirm all positive tests using a specific quantitative method.[29]

5-Aminolevulinic Acid

ALA can be measured directly[62] but is converted more usually into an Ehrlich-reacting pyrrole by condensation with a reagent, such as acetylacetone, after separation from PBG by two-stage anion exchange chromatography. A method for the measurement of PBG and ALA, based on that of Mauzerall and Granick, is available commercially (Bio-Rad Laboratories, Hercules, Calif.). An alternative photometric method has been proposed[20] for more rapid testing.

Compared with PBG procedures, interferences are much more common with ALA. For example, the acetylacetone derivatization step can form a compound with penicillin that reacts with Ehrlich's reagent.[80]

Method for the Determination of Porphobilinogen in Urine

The PBG procedure described here uses commercially available ion-exchange columns, but some laboratories might prefer to prepare an ion-exchange resin themselves.[18,19,134]

Principle

Urine is adjusted to a pH between 8 and 10, and an aliquot introduced onto an anion-exchange column. PBG adsorbs to the resin, whereas many interfering substances are flushed from the column with repeated water washes. PBG is then eluted with acetic acid. A modified Ehrlich's reagent is added to the eluate, which produces the classic "rose-red" color with pyrroles such as PBG. The color reaction is quantified with a spectrophotometer, and elevated results are scanned for evaluation of possible interferences.

Reagents

1. PBG anion-exchange columns (Bio-Rad Laboratories, Hercules, Calif.)
2. Acetic acid, 1 mol/L
3. Ehrlich's aldehyde reagent. Dissolve 1.0 g 4-dimethylaminobenzaldehyde in 42 mL of glacial acetic acid. Add 8 mL of 70% perchloric acid. This reagent should be used within 30 minutes of preparation.

Quality Control

No commercial quality control material is available. A suitable control can be prepared by dissolving a known amount of PBG (Sigma Chemical Co., St Louis) in normal urine. An added amount of approximately 20 mg/L (88 µmol/L) is suitable. Before adding PBG, urine should be centrifuged and gentamicin sulfate added (2 mL of a 40 mg/mL solution per liter of urine) and the pH adjusted to 7 to 7.5. Control material prepared in this way and stored in aliquots at –20 °C is stable for up to 1 year. Laboratories performing this assay should belong to an appropriate external quality assessment scheme.

Procedure

1. Check specimen pH with indicator paper. If necessary, adjust pH to be within an interval of 8 to 10.
2. Prewash column two times with 10 mL of distilled water.
3. Introduce a 1.0 mL aliquot of urine onto the column and drain.
4. Wash with 10 mL distilled water three times, draining completely between washes. Discard the washings.
5. Add 4.0 mL of 1 mol/L acetic acid to the column and elute (collect all of the eluate). Discard the columns.
6. Add 4.0 mL Ehrlich's reagent; mix and allow to stand at room temperature for 10 minutes.
7. Immediately read the absorbance in a spectrophotometer at 555 nm, using a 1 cm cell, against a blank prepared by mixing equal volumes of acetic acid (1 mol/L) and Ehrlich's reagent. The color is unstable and decreases by about 10% within 20 minutes. The method is linear up to an absorbance of 0.75.
8. Scan all elevated results. The PBG chromogen has a maximum around 555 nm with a slightly lower peak at 525 nm. The ratio of the absorbances (A_{525}/A_{555}) should be near 0.8. Comparison with a quality control sample may help. Maxima at other locations and a disproportionate ratio suggest that interferences are present and that results should be interpreted with caution.

Calculations

$$\mu\text{mol PBG/L} = A \times \frac{4 \times 1000}{0.144 \times 226}$$

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

where *A* is the absorbance at 555 nm, 4 is a dilution factor (1.0 mL of urine eluted with 4.0 mL acetic acid), and 0.114 is the absorbance of 1.0 mg/L of the chromogen at 555 nm in a 1 cm cell. Multiplication by 1000 and division by the molecular weight of PBG (226) converts to SI units (μmol/L).

Interpretation

Reference intervals are given in Table 32-3 in Chapter 32. Scanning the spectrum is essential if interferences are to be identified. Imipenem, for example, often gives a peak at 580 nm with Ehrlich's reagent.[147] The coefficient of variation at the cutoff of 9 μmol/L is approximately ±10%, but becomes considerably less precise at lower concentrations. For this reason, very dilute urines (creatinine <1.5 μmol/L) are unsuitable.

Urinary PBG that is raised at least 2 to 3 times the upper reference limit is diagnostic of an acute porphyria. However, porphyria is not necessarily the cause of symptoms (see discussion in the investigation of acute porphyria section). Further investigation is necessary to identify the type of porphyria. Normal PBG excretion in the presence of symptoms provides very strong evidence against those symptoms being caused by acute porphyria.

Analysis of Porphyrins in Urine and Feces

Methods for porphyrin fractionation are complex and time consuming and not available in every laboratory. For this reason, simple qualitative screening tests are often used to exclude the majority of specimens that do not require further investigation from the few that justify fractionation of the individual porphyrins. Screening tests in which extracts of urine or feces are examined visually for typical red-pink fluorescence of porphyrins lack sensitivity and should not be used.[27] Methods based on spectrophotometric scanning of acidified urine or fecal extracts for the presence of the Soret band are recommended and yield semiquantitative information.[29] Quantitative fluorometric methods are also available.[8]

All methods for the fractionation of porphyrins are based on the different solubilities of individual porphyrins because of their different β-substituents, and to a lesser extent on the substituent order around the macrocycle. Thus methods include differential extraction with solvents, paper and thin layer chromatography, and high-performance liquid chromatography (HPLC).[45,128] Solvent extraction methods yield only limited and sometimes misleading information and should not be used.[30] Reversed-phase HPLC is the current method of choice and separates all porphyrins of clinical interest, including isomers and metal chelates without the need for prior methylation.[5,74,123] Spectrophotometric or fluorometric detection can be used; the latter has superior sensitivity and specificity and is preferred.

Semiquantitative Method for Total Porphyrin in Urine

This simple method for total urine porphyrins uses scanning spectrometry.

Principle

Acidified urine is scanned for peak absorbance caused by the Soret band of porphyrins. Acidification of urine intensifies absorbance, facilitates conversion of porphyrinogens to porphyrins, and dissociates metal-porphyrin chelates. Thus total porphyrin can be detected by spectrophotometry and estimated semiquantitatively, provided correction is made for background absorbance.[8]

Quality Control

Material is available commercially (for example, Lyphocheck urine control; Bio-Rad laboratories, Hercules, Calif.). This semiquantitative method gives concentrations that are lower than the target value quoted by the manufacturer. Laboratories should belong to an appropriate external quality assessment scheme.

Procedure

1. Mix urine to resuspend any sedimented material and an aliquot (4.0 mL) is mixed with 1.0 mL concentrated hydrochloric acid (SG 1.18, Analytical Grade). Porphyrins adsorb strongly to calcium phosphate and other precipitates that may form in urine. It is essential that particulate matter is not discarded before the addition of concentrated hydrochloric acid.
2. Clarify by centrifugation and transfer clear supernatant to a 1 cm spectrophotometer cell.
3. Record the absorption spectrum between 350 nm and 450 nm against air in the reference cell.

Calculation

If a peak is present in the 400 nm region, the total porphyrin concentration is

$$A \times 2500\ \text{nmol/L}$$

where *A* is the peak absorbance above a baseline drawn between two suitable points (Figure 32-3) and the factor (2500) is derived from the volume of urine, the volume of acid, and a millimolar absorptivity of 500, which is approximately that of a 7/1 (mol/mol) mixture of coproporphyrin and uroporphyrin in 2.3 M HCl. The porphyrin composition of this mixture resembles that of normal urine.

Interpretation

Reference values are given in Table 32-3 in Chapter 32. The method is reproducible but only semiquantitative because inaccuracies are produced by the correction for background absorbance, particularly at low porphyrin concentration, and by variation in the porphyrin composition of urine in disease. The detection limit depends on the amount of background absorbance but concentrations of approximately 50 nmol/L should be detected in urine of normal color. Ideally, concentrations should be expressed as a ratio to creatinine concentration to correct for urine concentration. The molar absorptivities of the individual porphyrins were as

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

determined by Rimington.[121] The method of Blake et al[8] gives higher porphyrin concentrations.

Very occasionally, urine contains substances that produce a very high background absorbance, making identification of any peak in the 400 nm region difficult. Such samples require analysis by alternative methods, such as HPLC.

Increased concentrations require further investigation to identify individual porphyrins; porphyria should not be diagnosed on the basis of increased total porphyrin alone.

Semiquantitative Method for Total Porphyrin in Feces

This simple method for total fecal porphyrins uses scanning spectrometry after extraction.

Principle

Total porphyrin is determined by spectrophotometric scanning of an acidic extract of feces from which red-fluorescent pigments derived from dietary chlorophyll, which also absorb light at around 400 nm, are first removed by extraction with diethyl ether.[91]

Quality Control

No commercial control is available. A homogenized normal sample and one with a high porphyrin concentration should be divided into aliquots (about 0.5 g) to prepare control samples to include with each batch of analyses. Samples stored at −20 °C are stable for up to 1 year. Laboratories should belong to an appropriate external quality assessment scheme.

Procedure

1. Accurately weigh to the nearest 0.1 mg a small aliquot of feces (25 to 100 mg) in a glass-stoppered tube. Prior homogenization of the fecal sample is not necessary as long as the aliquot is removed from an area that appears reasonably uniform to the naked eye. Liquid samples are unsuitable for analysis.
2. Add concentrated hydrochloric acid (1.0 mL); vortex mix until all particles are disintegrated; add diethyl ether (3.0 mL); vortex mix to form a uniform emulsion; add distilled water (3.0 mL) and vortex mix for 30 seconds. Porphyrins are rapidly destroyed by peroxides, which accumulate in diethyl ether and similar solvents. Analar grade diethyl ether contains <0.000015% ether peroxides and is suitable for use. It should be stored in the dark and discarded after 2 months.
3. Separate the phases by centrifugation and transfer the lower aqueous phase to a glass spectrophotometer cell using a glass Pasteur pipette.
4. Record the absorption spectrum between 350 nm and 450 nm using air in the reference cell. For samples with a high porphyrin concentration or high background absorbance, dilution with 2.5 M HCl might be necessary.
5. Determine the dry weight of the sample by placing about 200 mg wet weight of feces onto a preweighed glass slide and weigh to the nearest 0.1 mg. Dry to a constant weight in an oven (105 °C for 16 hours), microwave oven (medium power for 15 minutes in a 850 kW oven), or rotary evaporator. Whichever method is used, careful calibration of the technique is required. After cooling, weigh the slide of feces to obtain the dry weight.

Calculation

If a peak is present in the 400 nm region, the total porphyrin is calculated

$$\text{Total porphyrin (nmol/g dry weight)} = \frac{A \times 4.5 \times \text{wet weight}}{0.33 \times \text{weight taken for analysis} \times \text{dry weight}}$$

where A is the peak absorbance measured above a baseline drawn between two suitable points (Figure 32-3), 0.33 is the average micromolar absorptivity for a mixture of protoporphyrin and coproporphyrin (3/1; mol/mol) in 2.5 M HCl, and 4.5 is the volume of the aqueous phase in mL and all weights are in grams.

Interpretation

Reference values are given in Table 32-3 in Chapter 32. The expression of concentration on a dry weight basis corrects for the moisture content of feces. The procedure may be simplified with little loss in sensitivity or specificity by omitting the drying stage and using 50 nmol/g wet weight as the upper reference limit.[26] Total fecal porphyrin determined by this method, unlike most tests based on solvent extraction, includes uroporphyrin.[126]

Very occasionally, feces contain substances that produce a very high background absorbance, making identification of any peak in the 400 nm region difficult. Such samples require analysis by alternative methods such as HPLC.

Increased total fecal porphyrin concentration requires further investigation by fractionation, identification, and quantification of individual porphyrins using a technique such as HPLC, which resolves coproporphyrin I and III isomers. Porphyria should never be diagnosed on the basis of raised total fecal porphyrin alone.

HPLC Fractionation of Porphyrins in Urine and Feces

This method for urine and fecal porphyrins uses sample preparation, HPLC separation, and fluorometric detection.

Principle

Porphyrins are separated by reversed-phase HPLC using a C_1-Hypersil*R* column with gradient elution.[89] Porphyrins are trapped in the hydrophobic stationary phase and remain trapped there until the mobile phase becomes more lipophilic. Porphyrins of increasing lipophilicity are sequentially eluted with a solvent of increasing methanol concentration. The order of elution depends on the number of ionized carboxyl groups on the porphyrin ring. Uroporphyrin is the most water soluble (i.e., hydrophilic) and elutes first followed by increasingly lipophilic heptacarboxylate,

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

hexacarboxylate, pentacarboxylate porphyrin, and coproporphyrin. The column eluent passes through a flow cell of a fluorometer, where the eluting porphyrins are identified by comparing their characteristic elution times with those obtained from reference porphyrins. The magnitude of the resulting fluorescence signal is proportional to the concentration of the eluting porphyrin.

Calibration

Calibration of porphyrin methods is problematical. Not all porphyrins of clinical interest are available commercially. One approach is to calculate the peak area of each porphyrin and express it as a percentage of the sum of the areas of all porphyrins identified on the chromatogram and to multiply by the total porphyrin concentration of the sample as determined by a quantitative/semiquantitative method. This approach can be criticized on the grounds that the total porphyrin result is influenced by the porphyrin composition of the sample and the fact that each porphyrin differs in absorbance and fluorescence. A marker kit is available commercially (Porphyrin Marker Kit from Porphyrin Products, Logan, Utah). However, this preparation is intended as a marker for peak identification, the concentration of each porphyrin is stated to be only within 10% of the quoted value, and it does not contain any porphyrins of the III series.

The method described uses a commercially available mixture of porphyrin calibrators supplemented with uroporphyrin-III, coproporphyrin-III, and deuteroporphyrin-IX. The nominal value for the type I isomers in the working calibrator (derived from the commercial porphyrin mixture) is 400 nmol/L. For most purposes these values are adequate. Since the spectral properties of porphyrin isomers are identical, the III isomers of uroporphyrin and coproporphyrin are calibrated by reference to the peak areas obtained with the type I isomers. If accurate quantification is required, then the best approach is to calibrate the stock uroporphyrin-III and coproporphyrin-III solutions by spectrophotometry of suitable dilutions using the absorption coefficients determined by Rimington.[121] The concentrations of these two components in the working calibrator mixture are then calculated and used to calculate the concentrations of the type I isomers. Alternatively, commercially prepared working calibrators of uroporphyrin-I and coproporphyrin-I are available (Frontier Scientific, Logan, Utah).

Equipment

This procedure requires an HPLC system capable of producing a binary gradient at a flow rate of 1 mL/min, and coupled to a fluorometric detector. For separation, a 150 × 4.6 mm column containing 5 µ SAS-Hypersil*R* (Thermo-Hypersil, Bellefonte, Pa.).

Reagents

1. 1.0 M ammonium acetate buffer, pH 5.16. Dissolve 154 g of ammonium acetate in approximately 1.5 L of distilled water. Adjust pH to 5.16 by the addition of glacial acetic acid (approximately 45 mL). Make the volume up to 2 L with distilled water and mix well.
2. Mobile phase A—10% acetonitrile in 1.0 M ammonium acetate pH 5.16
3. Mobile phase B—10% acetonitrile in methanol
4. Stock uroporphyrin-III (approximately 360 µmol/L). Add 3 mL of 25% v/v hydrochloric acid to the contents of a 1 mg bottle of uroporphyrin-III octamethyl ester (Sigma Chemical Co., St. Louis). Store in the dark at room temperature for 4 days to allow hydrolysis to occur.
5. Stock coproporphyrin-III (approximately 500 µmol/L). Add 3 mL of 25% v/v hydrochloric acid to the contents of a 1 mg bottle of coproporphyrin-III tetramethyl ester (Sigma Chemical Co., St. Louis). Store in the dark at room temperature for 4 days to allow hydrolysis to occur.
6. Stock deuteroporphyrin-IX (approximately 310 µmol/L). Add 3 mL of 25% v/v hydrochloric acid to the contents of a 10 mg bottle of deuteroporphyrin-IX dimethyl ester (Sigma Chemical Co., St. Louis). Store in the dark at room temperature for 4 days to allow hydrolysis to occur.
7. Working porphyrin calibration mixture. Add 5 mL of 0.27 mol/L hydrochloric acid to a vial of Porphyrin Marker Kit (Frontier Scientific Ltd., Logan, Utah). Mix to dissolve, then transfer to a 25 mL volumetric flask. Add 30 µL of the uroporphyrin stock, 20 µL coproporphyrin stock, and 50 µL of deuteroporphyrin stock. Note that these amounts are approximate; aim to produce a chromatogram in which the peak heights of all porphyrins are similar. Some experimentation may be required. Make up to the mark with 0.27 mol/L hydrochloric acid and mix. Store 1 mL aliquots at −20 °C; stable for at least a year.

Preparation of Samples

Samples should be prepared on the day of assay.

Urine. Add 100 µL of concentrated hydrochloric acid (specific gravity 1.18) to 1 mL of urine. Mix well and remove any visible insoluble material by centrifugation. Porphyrins adsorb strongly to calcium phosphate and other precipitates that may form in urine. It is therefore essential that particulate matter is not discarded before the addition of concentrated hydrochloric acid.

Feces. Prepare as for the semiquantitative spectrophotometric scanning procedure. The extract should be prepared on the day of analysis.

Spiked samples. To assist peak identification, it is recommended that all specimens should be analyzed both alone and mixed with an equal volume of working calibration mixture.

Quality Control

Material with elevated concentrations of uroporphyrin-I and coproporphyrin-III is available commercially (Lyphocheck urine control, level-II; Bio-Rad Laboratories, Hercules, Calif.). Laboratories should participate in a suitable external quality assurance scheme.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

Procedure

1. Connect the column to the HPLC equipment and prime with mobile phases A and B according to the manufacturer's instructions.
2. Run mobile phase A at a flow rate of 1.0 mL/min with the fluorometric detector set to an excitation wavelength of 404 nm and emission wavelength of 628 nm until a steady baseline is obtained.
3. Inject 100 µL of sample onto the column. Each analytical run should consist of calibrator, quality control, and patient samples both neat and spiked with calibrator.
4. Elute with a linear gradient from 0% B at time zero to 70% B at 30 minutes. Elute isocratically with 70% B for a further 10 minutes. Some slight adjustment to the elution conditions may be necessary for each batch of SAS-Hypersil if optimum resolution is to be obtained. Record the chromatograph using a chart recorder or store data on a PC.
5. Run mobile phase A (i.e., 0% B) for 10 minutes to reestablish starting conditions, then inject the next sample.
6. When all samples have been run, flush the column with a gradient (80% B initially to 0% B at 10 minutes), distilled water for 15 minutes, then methanol for 15 minutes. Close down the instrument.

Calculation of Porphyrin Concentrations and Interpretation

Figure 32-4, *A* shows a typical chromatogram for the working calibrator mixture. Chromatograms of the urine and fecal samples are first inspected visually and the peaks identified by comparison of the retention times with those of the porphyrins in the working calibrator mixture. Peak identification is aided by comparison with the chromatogram obtained for the corresponding spiked sample. If the porphyrin content of the sample is very high, then it may be necessary to rerun a diluted sample both neat and spiked with the calibrator—if the peaks are to be identified with confidence. Uroporphyrins I and III and coproporphyrins I and III can be easily identified since these compounds are present in the working porphyrin calibrator. Although the calibrator contains heptacarboxylate porphyrin, it is the I isomer, whereas the heptacarboxylate porphyrin that accumulates in PCT is mainly the III-isomer. The spiked sample will contain two heptacarboxylate porphyrin peaks next to each other. Several isocoproporphyrins may be found in feces of patients with PCT,[39] some of which may not be completely resolved: hydroxyethyl- and deethyl-isocoproporphyrin elute, just before coproporphyrin-I; isocoproporphyrin and dehydroisocoproporphyrin elute, just after coproporphyrin-III and before deuteroporphyrin-IX. Unfortunately the isocoproporphyrins are not available commercially. The remaining peaks, which elute after dehydroisocoproporphyrin, are all dicarboxylic porphyrins and in order of elution it is usually possible to detect deuteroporphyrin, pemptoporphyrin, mesoporphyrin, and protoporphyrin; tricarboxylic porphyrins and other unidentified peaks are often seen in this region.

For diagnostic purposes, quantification of individual porphyrins is rarely necessary, particularly if the concentrations are clearly elevated. Table 32-5 in Chapter 32 shows expected findings in the various types of porphyria and reference values for individual porphyrin fractions are given in Table 32-3. There is considerable variation in the reference values quoted in the literature,[144] probably a consequence of the difficulties in calibration discussed above. Figure 32-4 shows typical profiles from patients with various types of porphyria. Ideally, each laboratory should establish its own reference intervals.

Using the chromatogram for the working calibrator, calculate the concentration of uroporphyrin-III in the calibrator from the peak area of uroporphyin-I, assuming that the concentration of uroporphyrin-I is 400 nmol/L:

$$\text{Concentration of uroporphyrin-III (nmol/L)} = \frac{\text{Peak area uroporphyrin-III} \times 400}{\text{Peak area of uroporphyrin-I}}$$

Similarly, calculate the concentrations of coproporphyrin-III and deuteroporphyrin by reference to coproporphyrin-I and mesoporphyrin, respectively, assuming their concentrations are each 400 nmol/L.

Use these values to calculate the concentrations of porphyrins in the urine and fecal samples as follows:

For urine: Urine porphyrin concentration in nmol/L is given by

$$\frac{\text{Peak height or area of unknown} \times \text{Concentration of calibrator (nmol/L)} \times 1.1}{\text{Peak height or area of calibrator}}$$

Where 1.1 allows for the dilution of 1 mL urine with 0.1 mL of concentrated hydrochloric acid.

For feces: Fecal porphyrn in nmol/g dry weight is given by

$$\frac{\text{Peak height or area of unknown} \times \text{Concentration of calibrator (nmol/L)} \times 4.5 \times 100}{\text{Peak height or area of calibrator} \times \text{W (g)} \times \text{\% dry wt}}$$

where 4.5 is the volume in milliliters of the aqueous phase of the extract, W(g) is the weight of feces taken for assay in grams, and the percent dry weight is determined as described for the semiquantitative total porphyrin method.

Quantitation of dicarboxylate porphyrins is complicated by the presence of a large number of compounds that are not available commercially. One approach is to add the concentrations of all of these porphyrins together and report a "total dicarboxylate porphyrin fraction" by summation of the individual porphyrins calculated from the mesoporphyrin peak in the calibrator mixture.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

The extraction method for fecal porphyrins results in some interference with the chromatography because of the proportion of the diethyl ether dissolving in the aqueous phase. As a result, an extra peak elutes just before the uroporphyrin position. This peak contains any uroporphyrin in the sample, up to 50% of the heptacarboxylate porphyrins, and smaller amounts of hexacarboxylate and pentacarboxylate porphyrins.

Methods for Blood Porphyrins

The methods described below all require a spectrofluorometer fitted with a red sensitive photomultiplier. If such equipment is not available locally, samples should be referred to a specialized laboratory, because erythrocyte and plasma measurements are required rarely for the urgent assessment of acutely ill patients.

Determination of Erythrocyte Total Porphyrin

This method for erythrocyte total porphyrin uses double extraction and fluorometry.

Principle

This method is that described by Piomelli[112,113] as modified by Blake et al.[8] Porphyrins are extracted and hemoglobin and other proteins precipitated by mixing diluted blood with a diethyl ether–acetic acid mixture. Porphyrins are then back-extracted into hydrochloric acid and measured fluorometrically.

Reagents

1. Freshly prepared diethyl ether–glacial acetic acid (4/1; vol/vol). Porphyrins are rapidly destroyed by peroxides, which accumulate in diethyl ether and similar solvents. Analar grade diethyl ether contains <0.000015% ether peroxides and is suitable for use. It should be stored in the dark and discarded after 2 months.
2. 2.7 mol/L hydrochloric acid.
3. Uroporphyrin calibrator (12.0 nmol/L). Dilute uroporphyrin-I fluorescence calibrator (602 nmol/L) (Frontier Scientific Ltd., Logan, Utah) fiftyfold with 2.7 M hydrochloric acid and store aliquots in the dark at 4 °C (stable for up to 6 months).

Quality Control

No commercial control material is available. Normal and abnormal samples are divided into 0.1 mL aliquots, which when stored at −20 °C, are stable for 6 months. Alternatively, quality control material may be prepared by adding protoporphyrin to normal blood.[8]

Procedure

1. Add whole blood/packed cells (0.05 mL) to physiological saline (0.45 mL) in a glass or polypropylene tube, vortex mix, and while mixing continue to add 5 mL of the diethyl ether–acetic acid reagent. Continue to vortex for at least 15 seconds, centrifuge, and decant the whole supernatant carefully into a fresh tube.
2. Add 2.7 mol/L HCl (3.0 mL), vortex mix, and allow phases to separate, either by centrifugation or by leaving for 30 minutes in the dark.
3. Transfer the lower aqueous phase to a suitable cuvet using a glass Pasteur pipette.
4. With the emission wavelength of the spectrofluorometer at 602 nm, record the excitation spectrum from 350 nm to 450 nm. Similarly, scan the uroporphyrin calibrator.
5. If whole blood was used, determine the hematocrit.

Calculation

For both sample and calibrator, measure the vertical peak height (H) in millimeters above a line joining the points at 380 nm and 430 nm. If the sample used was whole blood, calculate the total porphyrin (as nmol/L erythrocytes) concentration as follows:

$$\frac{H_{sample} \times \text{Concentration of calibrator (nmol/L)} \times 0.177}{H_{calibrator} \times \text{hematocrit}}$$

where the factor 0.177 allows for the ninetyfold dilution of the sample, conversion from nmol/L to μmol/L, and the fact that protoporphyrin (the main porphyrin in blood) is about half as fluorescent as uroporphyrin at equivalent concentrations in 2.7 mol/L HCl at the emission wavelength used.

If packed cells were used in place of whole blood, then omit the hematocrit value from the above equation.

Interpretation

Reference intervals are given in Table 32-3 in Chapter 32. Total erythrocyte porphyrin concentrations are increased in EPP, CEP, the rare homozygous variants of the autosomal dominant porphyrias, iron deficiency, hemolytic anemia, some other forms of anemia, and lead poisoning. A normal total porphyrin concentration excludes the diagnosis of EPP. Distinction between EPP and other causes of increased erythrocyte total porphyrin concentration requires differentiation between protoporphyrin and its zinc chelate because the acidic conditions of this assay dissociate the zinc chelate and provide only a measure of total porphyrin.

Qualitative Determination of Zinc-Protoporphyrin and Protoporphyrin

This qualitative method for ZPP and protoporphyrin uses extraction and fluorometry.

Principle

To preserve the zinc chelate, neutral or basic extraction conditions are required. Diluted cells are mixed with ethanol, which precipitates hemoglobin and other proteins and extracts porphyrins without dissociating heme from hemoglobin.[55] The extract is scanned in a spectrofluorometer to

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

distinguish the emission maxima of protoporphyrin from its zinc chelate.

Reagent

95% (vol/vol) aqueous ethanol.

Sample and Quality Control

This procedure uses the same sample and quality control as the total blood porphyrin measurement.

Procedure

1. Add whole blood or packed cells (0.05 mL) to distilled water (0.2 mL) in a polypropylene tube and mix thoroughly.
2. Pipette 0.05 mL of this mixture into 95% (vol/vol) aqueous ethanol (1.0 mL), mix immediately, and continue vortex mixing for 15 seconds.
3. Centrifuge immediately to form a pellet of the precipitated protein.
4. Transfer the clear supernatant to a suitable cuvet and record the fluorescence emission spectrum between 550 nm and 650 nm at an excitation wavelength of 415 nm.

Interpretation

Emission peaks for zinc-protoporphyirn and free protoporphyrin are 587 nm and 630 nm, respectively. If the main peak is at 587 nm, EPP is excluded, whereas a pronounced predominance of the peak at 630 nm confirms the diagnosis of EPP (see Figure 32-5). With experience, this test can be used to screen for EPP without the need for quantitative analysis. It is possible to quantify both zinc-protoporphyrin and protoporphyrin by measuring the peak heights at 587 nm and 630 nm above a constructed baseline if calibrator solutions of both protoporphyrins are prepared, providing allowance is made for a contribution of fluorescence from zinc-protoporphyrin at the maximum for free protoporphyrin.[28] A limitation of this method is that the efficiency of the extraction of zinc-protoporphyrin is only about 50%.[28]

Analysis of Plasma Porphyrins

Plasma porphyrins may be determined by fluorescence emission spectroscopy of saline-diluted plasma[25,58,116] or deproteinized extracts,[92] or by HPLC.[72] The first of these methods is simple and includes porphyrins that are bound covalently to plasma proteins.

Fluorescence Emission Spectroscopy of Plasma Porphyrins

This method uses the fluorescent emission of porphyrins when excited at 405 nm.

Principle

Porphyrins at neutral pH fluoresce in the 610 to 640 nm region; the wavelength of maximum emission depends primarily on the porphyrin structure but is also influenced by the nature of the porphyrin-protein complex. The method described[58] was introduced by Poh-Fitzpatrick[116] and is a useful initial investigation for suspected cutaneous porphyria.

Specimen

Plasma from EDTA or heparinized blood or serum is suitable. Specimens should be protected from light and are stable for at least 3 months at −20 °C.

Reagent

Phosphate buffered saline (PBS). Disodium hydrogen phosphate (0.01 mol/L) and sodium chloride (0.14 mol/L) adjusted to pH 7.40 with hydrochloric acid.

Quality control

No commercial quality control material is available but known positive and negative samples should be included in each run.

Procedure

1. Add plasma (0.1 mL) to PBS (0.9 mL) in a spectrofluorometer cuvet and mix by inversion.
2. Record the fluorescence emission spectrum between 550 nm and 650 nm, with an excitation wavelength of 405 nm.
3. Note the wavelength maximum for any peak above the background between 600 nm and 640 nm (see Figure 32-6).

The spectrofluorometer should be capable of detecting a small peak at a plasma porphyrin concentration of 10 nmol/L. For the determination of the emission maximum, the spectrofluorometer should be calibrated with a solution of coproporphyrin in PBS at pH 7.4, which gives an emission maximum at 615 nm. It is important to establish a reference interval by determining the maximum height above the background for normal plasma samples; most but not all will show no emission peak (see Figure 32-6).

Interpretation

Figure 32-6 shows typical fluorescence emission maximum wavelengths for the cutaneous porphyrias. The plasma in VP contains porphyrin covalently bound to protein with a fluorescence emission maximum at 624 to 628 nm.[116] In other porphyrias, porphyrin is noncovalently bound to albumin and hemopexin.[82] A normal fluorescence emission scan in plasma from a patient with clinically active skin lesions excludes all cutaneous porphyrias as their cause.[31,58] The scan may become normal in PCT and HCP as skin lesions heal, and the diagnosis may be missed unless individual porphyrins are also measured in urine and feces from such patients. In addition, the scan may be abnormal during an acute attack of AIP or HCP in the absence of skin lesions and is always abnormal in clinically manifest VP, whether skin lesions are present or not (Table 32-5).

The plasma porphyrin concentration may be increased in conditions in which porphyrin excretion is impaired, such as renal failure and cholestasis. Although plasma porphyrin

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

concentrations are usually higher in chronic renal failure with PCT than in renal failure alone,[115] unequivocal diagnosis of PCT in this situation is best achieved by fecal porphyrin analysis[60] or fractionation of plasma porphyrins by HPLC.[72]

Enzyme Measurements

Assay of the individual enzymes of the heme biosynthetic pathway is rarely required for the investigation of patients with symptoms of porphyria. However, measurement of enzyme activities is useful for family studies when the individual mutation cannot be identified or DNA analysis is not available, and for the identification of subtypes such as nonerythroid AIP and "homozygous" forms of autosomal dominant porphyrias. Erythrocytes are a convenient source of cytoplasmic enzymes (ALAD, HMBS, UROS, and UROD),[132,56,33,46] but assay of the mitochondrial enzymes (CPO, PPOX, and FECH)[34,66,127] requires nucleated cells, such as leukocytes or cultured fibroblasts.[25] Assays for enzymes that use porphyrinogens as substrates are particularly difficult, because the substrate is unstable, has to be prepared in-situ, and particularly with protoporphyrinogen undergoes nonenzymatic oxidation during the assay. However, erythrocyte HMBS measurement is relatively straightforward and is described in detail below.

Assay of Erythrocyte Hydroxymethylbilane Synthase (HMBS) Activity

This enzymatic assay determines the amount of porphyrinogens formed from an excess of added PBG over the course of 30 minutes.

Principle

Whole blood or packed red cells are hemolyzed and incubated with excess PBG for a fixed time then the reaction terminated (and proteins precipitated) with trichloroacetic acid. The acid also has the effect of oxidizing porphyrinogens to the fluorescent porphyrins. The porphyrins are measured fluorometrically and the enzyme activity calculated. The formation of HMB is rate limiting and both products (uroporphyringen-I formed spontaneously from HMB, and uroporphyrinogen-III formed from the action of UROS on HMB) are determined together. A potential limitation is the further action of the next cytoplasmic enzyme in the pathway (uroporphyrinogen decarboxylase) to form coproporphyrin, which will remain bound to the protein pellet and not be included in the final measurement.

Specimen

Either whole blood or packed cells are prepared from blood collected into EDTA. Samples can be stored for 6 months at −20 °C without any appreciable loss in enzyme activity.

Reagents

1. *Assay buffer.* Tris(hydroxymethyl)aminomethane (0.05 mol/L), pH 8.25 containing magnesium chloride (0.01 mol/L) and 0.1 % V/V Triton X-100. Stable for 3 months at 4 °C.
2. *PBG substrate.* Porphobilinogen (7.4 mmol/L) in assay buffer. Store aliquots at −20 °C; stable for 3 months.
3. Trichloroacetic acid (10% w/v)
4. *Uroporphyrin calibrator* (302 nmol/L). Mix uroporphyrin fluorescence calibrator (Frontier Science Ltd., Logan, Utah) with an equal volume of 10% w/v trichloroacetic acid. Stable in dark at 4 °C for 3 months.

Quality Control

No commercial control available. Aliquots of normal and abnormal blood are stable at −20 °C for at least 6 months.

Procedure

1. Pipette assay buffer (1.4 mL) and whole blood or packed cells (50 µL) into plastic tubes and mix. Include quality control samples and a blank containing 50 µL of water in place of sample. The calibrator is not taken through the whole assay procedure.
2. Preincubate at 37 °C for at least 10 minutes.
3. Add PBG substrate (50 µL), mix, and incubate at 37 °C for exactly 30 minutes.
4. Add ice-cold 10% (w/v) trichloroacetic acid (1.5 mL) and vortex mix for 15 seconds.
5. Centrifuge to form a pellet of the precipitated protein, transfer the clear supernatant into separate tubes, and incubate in the dark at room temperature for 30 minutes to allow oxidation of porphyrinogens.
6. Measure the fluorescence of each tube and of the uroporphyrin calibrator using an excitation wavelength of 404 nm and an emission wavelength of 599 nm.
7. If whole blood was used for the assay, determine the hematocrit.

Calculation

Subtract the blank reading from all samples (including calibrator), then calculate the enzyme activity (in nmol uroporphyrin/mL erythrocytes/hr) as follows:

$$\frac{\text{Fluorescence}_{\text{sample}} \times 36.2}{\text{Fluorescence}_{\text{calibrator}} \times \text{hematocrit}}$$

The factor 36.2 allows for the dilution of sample in the assay, the concentration of the uroporphyrin calibrator and conversion from 30 minutes to an hour.

If packed cells were used for the assay, then omit the hematocrit value from the above formula.

Interpretation

The reference interval for this method[156] (mean ± 2SD) is 20 to 42 nmol uroporphyrin/mL erythrocytes/minute at 37 °C. Ideally each laboratory should determine its own reference interval. HMBS activity is usually below the reference interval in AIP, except in the uncommon nonerythroid form, but there is overlap between activities in AIP and normal individuals.[119] After exclusion of families with nonerythroid AIP,

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

HMBS activity has been reported to have a sensitivity of 84% and a specificity of 77% for detection of AIP in patients without symptoms.[52] In France, the prevalence of abnormally low HMBS activities in the general population is about 1 in 800.[110]

For family studies, in which the incidence of AIP is quite high, the predictive values of positive and negative tests are reasonable and HMBS assay is helpful, although not foolproof, in assigning AIP status. In the general population, in which the incidence of disease-specific mutations in the *HMBS* gene is in the order of 1 in 15,000, the predictive values are too low for the test to be of any value.

HMBS activity falls markedly as red cells age, so that any shift in their age distribution will be reflected in measured activity. Increased erythropoiesis may raise activity sufficiently to mask an inherited deficiency. Measurement of erythrocyte HMBS activity is therefore not reliable for the presymptomatic detection of AIP in subjects who are hematologically abnormal, have received a recent blood transfusion, or are less than 1 year old. Activity may also be increased in liver disease and in chronic alcohol abuse.

DNA Analysis

Screening families for porphyria by DNA analysis is a two-stage process. First, the mutation that causes porphyria in the family under investigation needs to be identified by analysis of DNA from a family member in whom the diagnosis of a specific type of porphyria has been established unequivocally. Second, that patient's relatives are then screened for the mutation. The first part of this process is the more complex. Because most mutations are restricted to one or a few families, identification of a mutation in a new family almost always requires analysis of the entire gene or at least all exons with their flanking intronic sequences and the promoter region. Initial testing for a single mutation is worthwhile only in those countries where founder mutations predominate, for example, VP in South Africa and AIP in Sweden.

Mutation Detection

Two main approaches are used to analyze a gene for the presence of a mutation (see also Chapter 37). The gene may either be screened to find the region that contains the mutation and then only that region sequenced to identify the mutation. Or all regions of the gene likely to contain the mutation may be sequenced directly. Prior screening considerably decreases the amount of sequencing that is required, but this is becoming a less important consideration as DNA sequencing becomes cheaper and more straightforward with development of ever better automated fluorescence sequencers.

Denaturing gradient gel electrophoresis (DGGE), single strand conformational polymorphism (SSCP) analysis, heteroduplex analysis, and denaturing HPLC have all been used to screen the *HMBS* and other porphyria genes for mutations.* DGGE is currently the most widely used technique and has high sensitivity† but requires gradient gels and PCR primers with GC extensions. Denaturing HPLC, though still requiring amplification of the gene in small fragments (about 500 bp), is rapid, simple, and robust. It has been shown to have high sensitivity for detection of mutations in many genes[158] and has the potential to replace DGGE as the method of choice.

Once the mutation that causes porphyria in a family has been identified, relatives can be screened for its presence either by using one of the screening methods listed above, by direct sequencing of the region containing the mutation, or by some other mutation-specific method (see Chapter 37).

A method for identifying mutations in the human *HMBS* gene by direct sequencing is described below. The method can be adapted for other porphyria genes by using the appropriate amplification and sequencing primers. Primer sequences have been published for the *PPOX*,[150] *CPO*,[101] *UROD*,[102] *FECH*,[106] and *URO*[33] genes.

Mutation Analysis of the Human HMBS Gene by Direct Sequencing

PCR is used to amplify some of the exons of the *HMBS* gene, which are then sequenced using the Sanger method. If no mutations are found, the remaining exons and the 5′ intron are evaluated.

Principle

After extraction of DNA from whole blood, exons 3 to 15 of the *HMBS* gene are PCR-amplified in 4 overlapping fragments. These fragments are purified using gel extraction and then sequenced in one direction by the Sanger method using fluorescent ddNTPs and 10 sequencing primers. After removal of unincorporated terminators, the products are analyzed using an automated fluorescence sequencer. Electropherograms are read visually and any putative mutation is confirmed by sequencing new PCR products in the opposite direction. If no mutation is identified in the exon 3 to 15 region, the 5′ untranslated region and exon 1 are PCR-amplified and sequenced. All fragments are resequenced in the opposite direction if no mutation is found by sequencing in one direction.

Specimen Collection and Storage

A minimum of 0.5 mL (preferably 5 mL) of EDTA-anticoagulated blood is required. Samples are transported to the laboratory at ambient temperature (preferably within 72 hours of collection). DNA is extracted on receipt or blood is kept at −20 °C until analyzed. Blood, DNA, PCR products,

	T2723	ATGAGTGGACGGATGAGTGCATGG	
Exons 9-11	T2730	TTTAGCCTCCCTATGTCATTTTCC	61 °C
	F497	CGGTAGCATCCCAAGGTCT	
Exons 11-15	P7461	GAGGTGGTCCCATGCTTTGCG	61 °C
	C2735	GGACAGCAGCAACCCAGGCATCTG	

and completed sequencing reaction mixes are stored at −20 °C, as necessary.

Procedure

1. DNA is extracted from whole blood using the QIAamp DNA blood Mini Kit (Qiagen) according to the manufacturer's instructions.
2. Exons 3 to 15 of the *HMBS* gene are amplified in four overlapping fragments. The PCR reaction mixture contains a hot-start polymerase (HotStar [Qiagen]). Amplification is for 30 cycles using the primers and conditions listed in Table A31-1. If necessary, 5′UTR and exon 1 are also amplified (Table A32-1).
3. After amplification, a 5 μL aliquot of each reaction mixture is analyzed by 1.5% agarose gel electrophoresis in 40 mmol/L TRIS-acetate and 1 mmol/L EDTA buffer at pH 8.0, and visualized in UV light as ethidium bromide complexes using a transilluminator.
4. If the size of the PCR product is correct, the amount sufficient, and no contamination is detected, electrophoresis is performed on the remaining reaction mixture and the product is excised from the gel using a scalpel. Areas of the gel not being immediately excised are protected from UV light by placing foil under the gel to minimize nicking of DNA. The excised gel slice is placed in a preweighed 1.5 mL tube, which is then reweighed to determine the weight of the excised slice.
5. DNA is eluted from the gel slice into water after solubilization of the gel and adsorption of DNA onto a spin column using a gel extraction kit (Qiagen) according to the manufacturer's instructions, including the optional 5 minute incubation at stage 10, before centrifuging.
6. 5 μL aliquots of the eluted PCR products are analyzed by agarose gel electrophoresis to assess recovery and to give a qualitative guide to the amount of product required for sequencing. The concentration is estimated by comparing the brightness of the band with that of an appropriate DNA size marker.
7. According to the estimated concentration, take 1 to 7.5 μL of eluted PCR product (template) and add 0.5 μL of primer (3.2 to 5 pmol/μL), 2 μL of BigDye terminator mix, and sterile deionized H_2O up to 10 μL, according to the template volume. Add sequencing mix and cycle sequence according to the manufacturer's instructions (ABI PRISM BigDye Terminator v3.0 Cycle Sequencing Kit, Applied Biosystems). Sequencing primers and PCR templates are listed in Table A32-2.
8. Unincorporated dye terminators are removed using ethanol/sodium acetate precipitation as specified in the Cycle Sequencing Kit.
9. The sequencing reaction products are analyzed using an ABI Prism 3100 Genetic Analyzer.
10. Electropherograms are analyzed visually by comparison with normal sequence. Putative mutations are confirmed by repeating stages 1 through 6 to obtain a fresh template for sequencing in the opposite direction.

Comment and Interpretation

In a prospective study of 198 unrelated patients with proven AIP, this method detected a mutation in 97% of patients. Almost all mutations were detected by sequencing in one direction only; rarely was sequencing in the opposite direction required to reveal an abnormality. Because amplified genomic DNA is sequenced directly without subcloning, the risk of PCR artifacts is very low and is essentially eliminated by sequencing a new PCR product in the opposite direction to confirm each mutation. Complete gene deletions and large partial deletions that prevent the binding of primers are not detected by this method, because only the normal allele will be amplified for sequencing. Such dele-

tions or mutations that lie outside the regions that are sequenced may explain the failure to find an abnormality in all patients.

In most countries, about one third of the mutations that are identified will not have been reported previously in AIP and may represent rare polymorphisms rather than disease-specific mutations. Criteria that suggest that such novel mutations cause disease include production of a frameshift or stop codon, the absence of any other sequence abnormality in the gene, segregation with disease, and nonconservative change of an amino acid residue that is conserved between species and/or known to have a functional role in catalysis. Mutations of consensus bases in splice sites are also likely to be disease-specific, but ideally all putative splicing defects should be confirmed by analysis of mRNA. Proof that a missense mutation causes disease may require expression and characterization of the mutant enzyme in a prokaryotic or eukaryotic vector.

Identification of a Functional Polymorphism in FECH Gene

The method described below tests for the presence of the IVS3-48C FECH allele. This allele causes decreased expression of *FECH* because substitution of the T nucleotide at IVS3-48 by a C nucleotide leads to enhanced use of an alternative splice site with increased formation of an unstable mRNA for *FECH*.[63]

Principle

Intron 3 is amplified and the PCR product sequenced to identify the nucleotide(s) at position IVS3-48C. Identification is confirmed by sequencing a new PCR product in the opposite direction.

Specimen Collection and Storage

The specimen collection and storage for this method is the same as for mutation analysis of the *HMBS* gene.

Procedure

1. After extraction of DNA from whole blood (see above), intron 3 of the *FECH* gene is amplified using 30 cycles of PCR at 58 °C and the following primers: 5′-GTGTTGT GTGTCCTGAATCTT and 5′-GTCAAGGGATAACGC CTGGAG.
2. PCR products (585 bp) are processed as described for stages 3 to 7 of mutation analysis of the *HMBS* gene, except that the primers and primer concentrations used for sequencing are the same as those used for amplification of intron 3 of the *FECH* gene.
3. Remove unincorporated dye terminators and analyze sequence as described for stages 8 and 9 of mutation analysis of the *HMBS* gene.
4. Identify nucleotide(s) at IVS3-48C by inspection of electropherogram. Confirm by repeating stages 1 to 3.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

Comment and Interpretation

The IVS3-48C allele is carried by about 12% of the western European population. If it is not present in the partner of a patient with overt EPP, and they have not previously had a child with overt EPP, the risk that the couple will have a child with overt EPP is less than 1 in 50, where as if it is present, the risk is about 1 in 4. Investigation for the presence of the IVS3-48C allele in the parents of a child with overt EPP is usually not helpful, because the risk of overt EPP in subsequent children is 1 in 4 irrespective of whether the unaffected partner carries the low expression allele. Testing a newborn child for the low expression allele may also be useful for predicting the child's risk of later developing symptoms.

APPENDIX 33

Therapeutic Drugs and Their Management

Thomas P. Moyer, Ph.D., and Leslie M. Shaw, Ph.D.

ANALYTICAL METHODOLOGY

The following four methods are included here for the determination of the indicated therapeutic drugs:

1. Method 33-1. Determination of 10-hydroxy-10,11-dihydrocarbamazepine (MHC)
2. Method 33-2. Determination of Chloramphenicol
3. Method 33-3. Determination of Serum Lithium
4. Method 33-4. Simultaneous Determination of Cyclosporine, Everolimus, Sirolimus, and Tacrolimus

This section contains four analytical methods and three case studies.

METHOD 33-1. DETERMINATION OF 10-HYDROXY-10,11-DIHYDROCARBAMAZEPINE (MHC)

Principle

Serum is mixed with internal standard. 10-Hydroxy-10,11-dihydrocarbamazepine (MHC) and internal standard are extracted into 20% ethyl acetate, 80% chloroform, with a pH 9.0 buffer. The organic layer is transferred, evaporated, and reconstituted in HPLC mobile phase. The sample is analyzed by HPLC with ultraviolet detection.

Reagents

1. 0.1 mol/L phosphate buffer, pH 4.0: Mix 96 g potassium phosphate monobasic (KH_2PO_4) and 10 g potassium phosphate dibasic (K_2HPO_4) in 8 L of type I distilled water and adjust pH to 4.0 ± 0.5 with concentrated phosphoric acid (H_3PO_4).
2. Phosphate-TEA buffer, pH 7.0: Add 200 mL of 0.1 mol/L phosphate buffer, pH 4.0, to 600 mL type I distilled water and 10 mL of triethylamine (TEA). Mix thoroughly and adjust pH to exactly 7.0 with concentrated phosphoric acid. Transfer solution to a 1 L volumetric flask and bring to volume with type I distilled water. Filter this buffer solution through a 0.47 μm filter before using.
3. Extraction solvent—20% ethyl acetate in chloroform: Add 200 mL ethyl acetate to 1000 mL dispenser bottle. Add 800 mL chloroform and mix well.
4. Extraction buffer—0.2 mol/L borate buffer, pH 9.0: Add 38.1 g of sodium borate decahydrate ($Na_2B_4O_7 \cdot 10\ H_2O$) to 500 mL of water. Adjust with NaOH or H_3PO_4 to pH 9.0.
5. Mobile phase (2 L). Mobile phase and reconstitution solution: 15% acetonitrile, 85% phosphate-TEA buffer, pH 7.0.
6. Stock calibrator: To a 10 mL volumetric flask, add 10.0 mg of MHC and dilute to volume with methanol.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

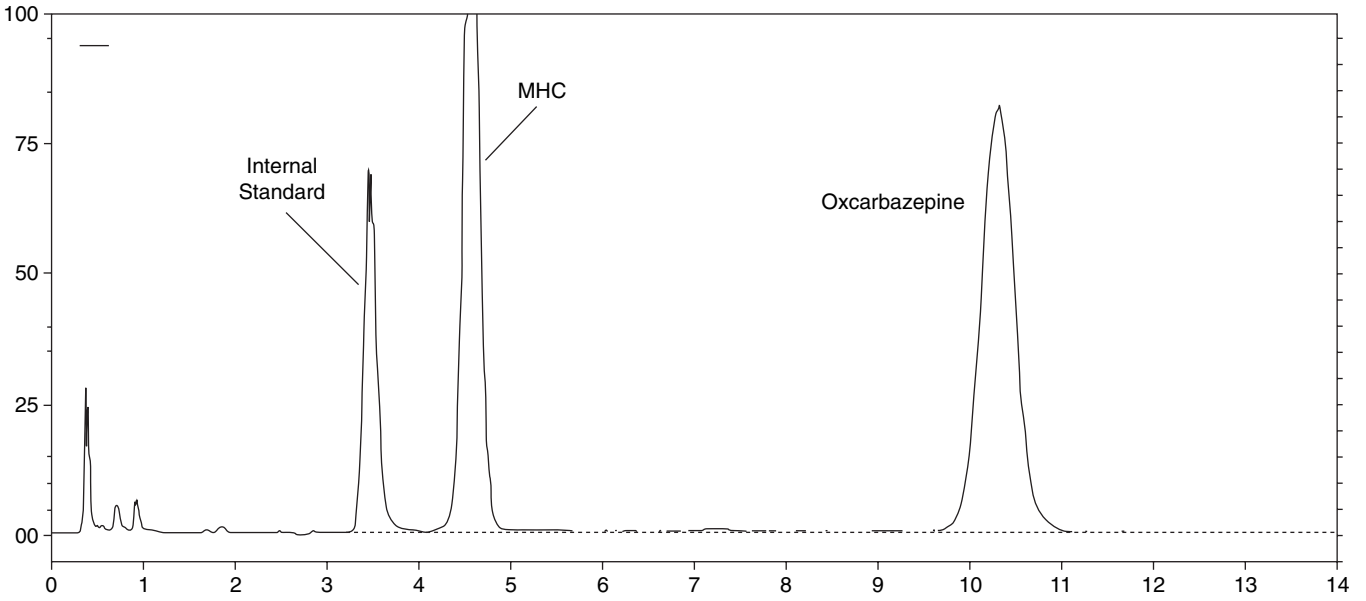

Figure A33-1 HPLC for oxcarbazepine metabolite (MHC). The peak at 3.46 minutes is the internal standard, the peak at 4.57 minutes is 10-hydroxy-10,11-dihydroxycarbamazepine (MHC), and the peak at 10.3 minutes is oxcarbazepine.

Dissolve and mix completely. Transfer to amber vial with Teflon-lined screw cap.

7. Internal standard: To a 10 mL volumetric flask, add 10.0 mg of 3,4-dihydro-3-methyl-2(1H)-quinazolinone (Sigma Chemical Co., St. Louis) and bring to volume with methanol. Dissolve and mix completely.

Equipment

This procedure requires the use of a high-resolution liquid chromatograph (HPLC) with a flow-through ultraviolet detector. A good system would consist of a pump capable of maintaining constant flow rate in the range of 1 to 2 mL/min, with variation in rate not to exceed ± 2% at pressures up to 3000 psi. Chromatography is performed on a Supelcosil 25 cm × 4.0 mm ID LC-18-DB 5 μ column. The ultraviolet detector should have a 1-cm flow cell of less than 10-μL volume capable of measuring absorbance at 0.001 A, with variance of ± 2%. Set the wavelength to 240 nm. The voltage output from the detector is integrated by an electronic integrator to generate the chromatogram shown in Figure A33-1.

Procedure

1. Thaw the aliquot calibrator and controls as needed. Invert calibrator, controls, and samples several times to mix before aliquoting into test tubes.
2. Aliquot 200 μL of standard, controls, and samples into appropriately labeled 12 × 75 mm glass test tubes.
3. Add 100 μL of working internal standard to each tube.
4. Add 6.0 mL extraction solvent to each tube. Vortex for 1 minute. Centrifuge for 2 to 3 minutes at 2500 rpm.
5. Carefully aspirate the aqueous layer off the top of each tube.
6. Pour the organic layer into a clean, appropriately labeled 16 × 100 mm tube. If it appears aqueous material is transferred, carefully pour the organic layer into another clean, labeled 16 × 100 mm tube.
7. Evaporate for 10 minutes with heat (30 °C to 35 °C); solvent must be completely evaporated.
8. Reconstitute remaining residue with 200 μL of reconstitution solution.
9. Transfer to appropriately labeled autosampler vials, and inject 10 μL on an HPLC system.

Levert H, Odon P, Robert H. LC determination of oxcarbazepine and its active metabolite in human serum. J Pharm Biomed Anal 2002;28:517–25.

Method 33-2. Determination of Chloramphenicol

Principle

Chloramphenicol and an internal standard, mephenesin, are extracted from alkalinized serum, plasma, or other biological fluids into diethyl ether. The extract is transferred to a clean tube, and the solvent evaporated. Quantification is accomplished by separating the reconstituted extract by HPLC, using an ultraviolet detector.

Reagents

1. Stock chloramphenicol calibrator. Chloramphenicol is obtained as either a diagnostic reagent or from alkaline hydrolysis of chloramphenicol succinate. Prepare a solution of 0.5 mg/mL in methanol. This solution is stable for 6 months if stored in a sealed container at 4 °C.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

Final Concentration (μg/mL)	Diluted Stock (mL) (mL)	Methanol (mL)
10	0.1	0.9
20	0.2	0.8
30	0.3	0.7
40	0.4	0.6

2. Working calibrators. Dilute 1.0 mL of the stock calibrator to a final volume of 5 mL with methanol. Prepare working calibrators as shown below. These diluted stock calibrators are stable for 1 month in sealed containers.
3. Internal standard. Dissolve 25 mg of mephenesin (Sigma Chemical Co., St. Louis) in 100 mL methanol. This solution is stable for 6 months if stored in a sealed container at 4 °C.
4. Tris 0.8 mol/L, pH 10.4. Dissolve 9.69 g of tris(hydroxymethyl)aminomethane (Tris) in water and dilute to a final volume of 10 mL. This solution is stable for 1 year in a sealed container.
5. Diethyl ether, reagent grade. Store in metal container. After can has been open for 1 month, discard by evaporation in a hood.

Instrumentation

This procedure requires the use of an HPLC with a flow-through ultraviolet detector. The mobile phase used is a mixture of 35 parts methanol and 65 parts water pumped at a flow rate of 2.0 mL/min. The ultraviolet detector is set to monitor 278 nm at 0.02 absorbance units full scale (AUFS).

Procedure

1. Into appropriately labeled 16 × 125 mm screw-capped culture tubes, add 100 μL of each diluted stock calibrator and evaporate to dryness at 40 °C using a gentle stream of nitrogen to remove evaporated solvent.
2. Add 100 μL of drug-free serum to each calibrator tube and mix.
3. Add 100 μL of specimen or control pool to an appropriately labeled tube.
4. To all tubes from steps 2 and 3, add 0.8 mL of Tris, 100 μL of internal standard, and 10 mL of diethyl ether.
5. Cap all tubes and gently tumble at a rate of about 20 inversions per minute for 10 minutes.
6. Separate the phases by centrifugation and transfer the ether layer (without carrying over any of the interface emulsion) to a 12-mL disposable polypropylene centrifuge tube.
7. Evaporate the ether with a gentle stream of nitrogen until a wet residue remains. Evaporation to complete dryness is not necessary and is too time-consuming.
8. Redissolve the residue in 100 μL of methanol and chromatograph.
9. Identify chloramphenicol by its retention time and quantify using either peak height or area.

Method 33-3. Determination of Serum Lithium

Principle

Lithium present in serum reacts with a substituted porphyrin (proprietary compound) in the presence of sodium hydroxide to form a red-colored complex (maximum absorbance at 510 nm). Equilibrium analysis of absorbance correlates with lithium concentration. Background due to presence of red chromophores is corrected by subtracting background measured at 480 nm.

Reagents

Reagents designed for use on an automated spectrophotometric analyzer are available from ThermoTrace, Victoria, Australia.

Procedure

Reagents are prepared in accordance with the manufacturers' instructions. An automated spectrophotometric analyzer is set up to mix 5 μL of serum sample, 50 μL of 0.5 mol/L sodium hydroxide, and 250 μL of porphyrin. This mixture is incubated for 120 seconds at 37 °C, then absorbance is measured at 480 nm and 510 nm. A calibration equation is created by correlating the absorbance difference ($A_{510} - A_{480}$) with reference calibrators in serum ranging from 0.1 to 3.0 mmol /L. Sample results are derived by application of the correlation equation to sample absorbance difference.

Method 33-4. Simultaneous Determination of Cyclosporine, Everolimus, Sirolimus, and Tacrolimus

Principle

Tacrolimus (Tac), everolimus (Ever), sirolimus (Siro), and cyclosporine are isolated from whole blood using a denaturing solution to lyse the blood cells and precipitate proteins. This denaturing solution also contains Ascomycin and cyclosporine G, the internal standards. Samples are mixed vigorously with the denaturing solution then centrifuged. The supernatant is transferred to an autosampler vial and approximately 200 μL is injected onto an HPLC column preceding tandem mass spectrometry quantification. A loading column captures the analytes, which are then eluted onto a second column to facilitate separation of the analytes from the void volume.

Continued.

Reagents

1. Chemical sources.
   Ammonium acetate from Sigma, Cat. # A-8920, ACS reagent grade.
   Zinc sulfate from Sigma, Cat. # Z-4750, minimum 99%.
   5 mg Tac (Prograf®, 5 mg/mL) ampule purchased from local pharmacy.
   Ever from Novartis Pharmaceutical.
   Siro from Wyeth-Ayerst Laboratories.
   Cyclosporine A from Sigma, Cat. # C-3662.
   Ascomycin from Sigma, Cat. # A-3835.
   Cyclosporine G from Sandoz Research Institute.
2. Stock standards.
   Tac, 0.1 mg/mL. Transfer the entire contents of one 5 mg/mL Tac ampule into a 50 mL volumetric flask and dilute to volume with methanol. Each lot must be analyzed to determine the actual content.
   Ever, 0.1 mg/mL. Accurately weigh 1.0 mg stock I Siro into a 10 mL volumetric flask and bring to volume with methanol.
   Siro, 0.1 mg/mL. Accurately weigh 1.0 mg stock I Siro into a 10 mL volumetric flask and bring to volume with methanol.
   Ascomycin, 0.1 mg/mL. Transfer the entire contents of one ampule into a 10 mL volumetric flask and dilute to volume with methanol.
   Cyclosporine A, 1.0 mg/mL. Accurately weigh 10.0 mg cyclosporine A into a 10 mL volumetric flask and dilute to volume with methanol.
   Cyclosporine G, 0.5 mg/mL. Accurately weigh 5.0 mg cyclosporine G into a 10 mL volumetric flask and bring to volume with methanol. Stable 2 years at –20 °C.
3. Intermediate stock standards.
   Tac, Ever, and Siro, 10 μg/mL. Add 2.5 mL of stock Siro and 2.5 mL of stock Tac to a 25 mL volumetric flask. Dilute to volume with methanol.
4. Denaturing solution with internal standards.
   Add 26 g zinc sulfate and 300 mL of type I water to a 1 L bottle. Dissolve the zinc sulfate by stirring. Add 700 mL methanol, 0.5 mL of 0.1 μg/mL Ascomycin, and 0.5 mL of 0.5 μg/mL cyclosporine G.
5. Calibrators.
   Low calibrator—Tac, Ever, and Siro, 10 ng/mL each, and cyclosporine, 100 ng/mL.
   Spike 2 L of whole blood with 2.0 mL of the intermediate Tac and Siro standard and 0.4 mL of 0.5 mg/mL cyclosporine. Mix thoroughly. Aliquot and freeze within 48 hours.
   High calibrator—Tac, Ever, and Siro, 50 ng/mL each, and cyclosporine, 500 ng/mL.
   Spike 2 L of whole blood with 10.0 mL of the Siro and Tac intermediate standard. Mix thoroughly and 2.0 mL of 0.5 mg/mL cyclosporine. Aliquot and freeze within 48 hours.
6. Quality control samples.
   Low control—Tac, Ever, and Siro, 5 ng/mL each, and cyclosporine 50 ng/mL.
   Spike 500 mL of whole blood (use outdated blood from Transfusion Medicine) with 0.25 mL of the Siro and Tac intermediate standard and 0.05 mL of 0.5 mg/mL cyclosporine. Mix thoroughly. Aliquot and freeze within 48 hours in 12 × 75 mm polypropylene.
   High control—Tac, Ever, and Siro, 25 ng/mL each, and cyclosporine, 400 ng/mL.
   Spike 500 mL of whole blood with 1.25 mL of the Siro and Tac intermediate standard and 0.4 mL of 0.5 mg/mL cyclosporine. Mix thoroughly. Aliquot and freeze within 48 hours.
   Mid-range control—Tac, Ever, and Siro, 12 ng/mL each, and cyclosporine, 200 ng/mL.
   Spike 4 L of whole blood with 4.8 mL of the Siro and Tacro intermediate standard and 1.6 mL of 0.5 mg/mL cyclosporine. Mix thoroughly. Aliquot and freeze within 48 hours.
7. Unextracted sample.
   Spike 0.02 mL of the intermediate Siro, Ever, and Tac standard and 0.04 mL of 0.5 mg/mL cyclosporine into 10 mL of denaturing solution plus 5 mL of type I water. Mix thoroughly. Aliquot and freeze within 48 hours.
8. HPLC mobile phases.
   Loading column mobile phase—50% methanol in 20 mmol/L ammonium acetate:
   Dissolve 3.08 gm of ammonium acetate in 2 L of 50% methanol : 50% water. The flow rate is 2.0 mL/min.
   Analytical column mobile phase—90% methanol in 20 mmol/L ammonium acetate:
   Dissolve 3.08 gm of ammonium acetate in 2 L of 90% methanol : 10% water. The flow rate is 0.20 mL/min.
   Note: Mobile phase concentrations may differ slightly from documented values based on variations in instrument performance and aging of column.
9. HPLC injector rinse solution:
   Mix 900 mL of methanol with 100 mL of type I water.
10. HPLC column:
    Phenomenex, SecurityGuard Guard Cartridge (Part #KJO-4282)

Procedure

1. Sample preparation.
   a. Transfer 0.5 mL of calibrators, controls, or patient samples, 0.1 mL of type I water, 0.75 mL of denaturing solution to 12 × 75 tubes. Mix the sample vigorously for 1 minute.
   b. Centrifuge tubes for 5 minutes at 3500 rpm. Transfer 0.6 mL of each sample to autosampler vials.
2. HPLC conditions:
   The HPLC is composed of two pumping systems connected through a switching valve. The switching valve is set to direct the loading mobile phase to the column at the start of the run. In this mode, the loading column eluate is directed to waste (as sample is injected, the ana-

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

lytes are retained on the loading column and inorganics [including the denaturing agent] are pumped to waste), while the analytical mobile phase bypasses the column and is continuously directed to the mass spectrometer source. At 0.5 minute into the run, the mobile phase is redirected by the switching valve to cause the analytical mobile phase to pass through the column in the reverse direction. This elutes the analytes from the columns directly into loading column into the analytical column. The analytical column serves to separate the analytes from the analytical column void volume. The analytical column eluate is continuously directed to the mass spectrometer source for analysis, while the loading solvent continues to pump to waste.

3. Tandem mass spectrometer conditions:
   Quantification by tandem mass spectrometry is based on the integrated peak areas of the Tac ion parent and daughter ions (Q1 = 821.6, Q3 = 768.5 amu), Ever ion parent and daughter ions (Q1 = 975.8, Q3 = 908.7 amu), Siro ion parent and daughter ions (Q1 = 931.4, Q3 = 864.3 amu), the Ascomycin internal standard ion parent and daughter ions (Q1 = 901.6, Q3 = 816.6 amu), the CyA ion parent and daughter ions (Q1 = 1220.0, Q3 = 1202.9 amu), and the CyG internal standard ion parent and daughter ions (Q1 = 1233.8, Q3 = 1215.7 amu) multiplied by a predetermined calibration factor. Calibration factors are calculated from the calibration standard at the time of calibration.

   Run an unextracted sample as the first injection of the day to confirm the instrument is running properly, all analytes are detected, and sensitivity is adequate.

   Run each calibrator, control, and patient sample and collect peak area output for each. A sample mass spectrogram is attached at Figure A33-2.

4. Calculation of results:
   LC-MS/MS calibration software is set up for the automatic calculation of the concentrations; however, they may be manually calculated using the following equations (Tac example):

$$\text{Calibration Factor (f)} = [\text{Concentration of Calibrator}] \times \frac{[\text{Area of 768.5 ion in Calibrator}]}{[\text{Area of 816.6 ion in Calibrator}]}$$

$$\text{Analyte Concentration (ng/mL)} = \text{f} \times \frac{[\text{Area of 816.6 ion in Sample}]}{[\text{Area of 768.5 ion in Sample}]}$$

   Review the output from each mass spectrogram to ensure baselines are assigned correctly; manually integrate the peaks if necessary.

   Check linearity of calibrators and acceptability of control samples. Plot controls in the electronic QC spreadsheet. The icon is a red and yellow target.

CLINICAL APPLICATIONS

Several case studies that apply the clinical principles and the pharmacology data described in Chapter 33 are presented here. They present typical problems the clinician and clinical laboratorian are faced with in daily practice.

CASE STUDY 1

Presentation

A 67-year-old woman weighing 80 kg has experienced congestive heart failure. She has no ventricular rhythm disturbances, so digoxin is indicated. She is also having significant pulmonary congestion because of congestive heart failure, and albuterol has been suggested to treat this problem. She is currently receiving furosemide to reduce her fluid load, K-lyte to avoid potassium depletion, and dopamine to control blood pressure. Her creatinine clearance is 40 mL/min. What loading and maintenance doses of digoxin and theophylline should you administer?

Resolution

This is a common case requiring adjustment of digoxin dose to account for reduced clearance. It also requires some thought about the effect of co-administered drugs.

Determining the Digoxin Dose

This problem is complicated because digoxin has a long normal half-life (almost 2 days), but it usually is dosed once each day (i.e., more frequently than once each half-life). Therefore we need to use equations (33A-1) and (33A-2) to estimate dose. The normal digoxin dose can be predicted by inverting equation (33A-1) to express dose:

$$C_{SS} = \frac{(D_0 \times f)e^{-kt}}{V_d(1 - e^{-kt})} \qquad (33A\text{-}1)$$

or

$$D_0 = \frac{[(C_{ss})(V_d(1 - e^{-kt}))]}{(e^{-kt} \times f)}$$

Parameter values needed to perform this calculation include: Css = 1.5 ng/L, Vd = 5 L/kg, τ = 40 h, and f = 0.7. Also, recall that the ideal time for specimen collection for digoxin monitoring is 8 hours after the dose to allow for equilibrium between serum and tissue concentrations; therefore t = 8 h.

Inversion of equation (33A-2) allows for calculation of the elimination constant, k

$$\tau_{1/2} = \frac{0.693}{k} \qquad (33A\text{-}2)$$

Continued.

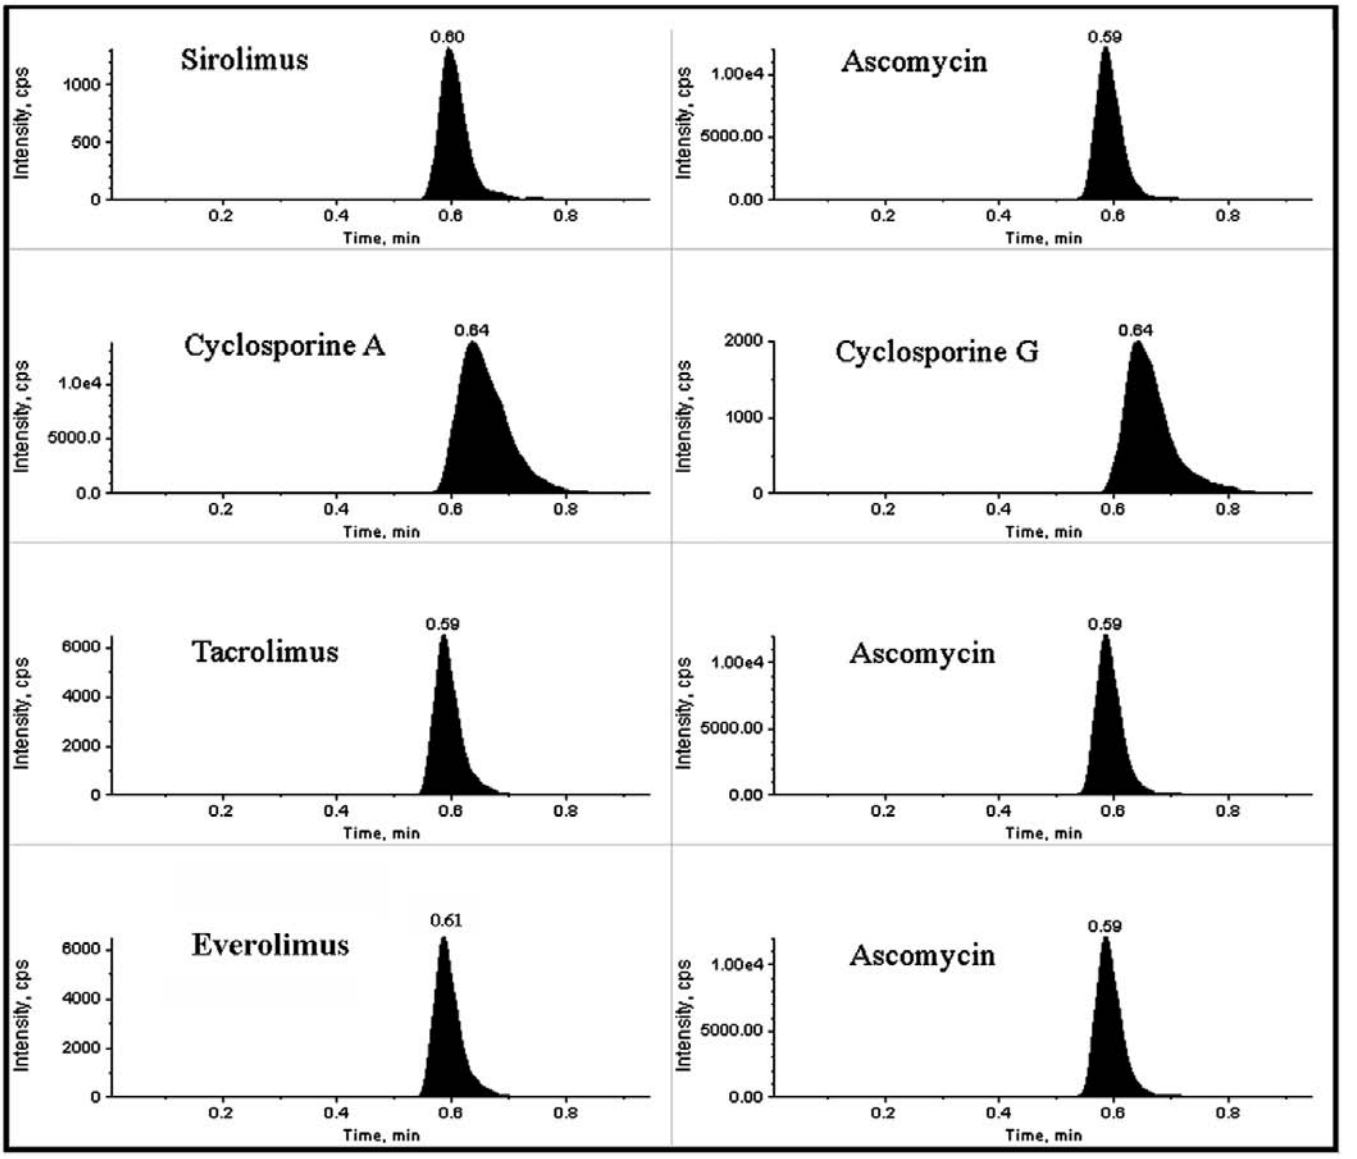

Figure A33-2 Daughter ion tandem mass spectrogram developed from the analysis of cyclosporine A, Ever, Siro, and Tac, and the internal standards Ascomycin and cyclosporine G.

CASE STUDY 1—cont'd

inverting

$$k = \frac{0.693}{\tau_{1/2}}$$

thus

$k = 0.0173\ h^{-1}$

Inserting all of the factors listed above into equation (33A-1) yields

$D_0 = 6.1\ \mu g/kg$

In this 80-kg patient, $D_0 = 6.1\ \mu g/kg \times 80\ kg = 488\ \mu g$. Therefore 0.49 mg of digoxin is administered per half-life (τ).

Digoxin Administration Dose

For patient convenience, digoxin is normally administered once each day. Because $\tau_{1/2}$ normally is 40 hours, the daily dose would be [0.49 mg]/[40 h] = 0.29 mg/d. Because digoxin is available in proprietary tablets containing 0.25 mg, such a dose would be adequate for the normal patient (in fact, based on the calculations shown above, 0.25 mg is the ideal dose for the typical 70-kg person).

This patient has significant reduction in renal function (clearance = 40 mL/min, or 40% of normal). Digoxin metabolism is predominantly affected by renal function. Reduced renal function prolongs digoxin's excretion half-life. This patient's actual half-life is calculated

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

CASE STUDY 1—cont'd

by adjusting the normal half-life ($\tau_{1/2} = 40$ hr) by the ratio of normal to actual renal clearance (100/40), giving an actual half-life for this patient of 100 hours (Note: the basis for this mathematical relationship is contained in equation [13] of Chapter 33). Reduced renal function does not have a pronounced effect on volume of distribution or the target serum concentration ($C_{ss} = 1.5$ μg/L), so inserting the new half-life ($\tau_{1/2} = 100$ hr) in equations (33A-1) and (33A-2) allows one to calculate the dose required for steady state

$$D_{SS} = 6.1\,\mu g/kg$$

Note that this is the same value as calculated for the normal half-life. Why is this? Because the elimination constant, *k,* and half-life, $\tau_{1/2}$, are interdependent—they effectively counter each other in the combination of equations (33A-1) and (33A-2). However, the daily dose must be reduced to accommodate the new half-life of 100 hours. The total dose predicted (0.49 mg) should be divided over 4.2 days (100 hours), indicating a dose of 0.12 mg/d. Conveniently, there is a proprietary product available to deliver such a daily dose.

Practical note: All calculated results described in this case study are based on estimates. After five half-lives, measure the drug concentration in the blood and make adjustments in dose to account for real variances that occur from patient to patient. Also, as the patient's health improves, renal function is likely to normalize. The daily dose should be increased to account for improvement in renal function.

Do we need to adjust the dose to accommodate for other co-administered drugs? Albuterol does not alter digoxin metabolism or clearance, nor do furosemide or dopamine. No adjustments are needed for these co-administered drugs.

CASE STUDY 2

Presentation

A 52-year-old, 70-kg male patient with chronic epilepsy has experienced a myocardial infarction with accompanying ventricular fibrillation. This patient has been maintained for years on 240 mg of phenobarbital (3 mg/kg/day), yielding a peak phenobarbital concentration of 35 μg/mL to control his epilepsy. On admission, it is determined that he will be treated with lidocaine to gain temporary control of ventricular rhythm. What dose of lidocaine do you administer as a loading dose, what is the maintenance dose, and how frequently is it administered? Electrophysiology studies indicate that his ventricular tachycardia was well controlled by procainamide. Calculate the loading and maintenance doses and dosing interval to achieve a peak blood concentration in the range of 8 to 10 μg/mL. After five half-lives, you measure his procainamide concentration and it is 6 μg/mL (6 mg/L), and the *N*-acetylprocainamide (NAPA) concentration is 5 μg/mL. What does this mean? After implementing the appropriate antiarrhythmic drug at an optimal dose, does his phenobarbital dose need to be changed?

Resolution

Resolution of this case will require the estimation of the lidocaine dose, calculation of the maintenance dose of lidocaine, and an estimation of the procainamide dose. No change is needed in the phenobarbital dose because lidocaine and procainamide do not influence phenobarbital pharmacodynamics. However, phenobarbital affects lidocaine and procainamide metabolism, so an adjustment in dose of both drugs is necessary.

Estimation of the Lidocaine Dose

Equation (33A-3) and data from Table 33-3 of Chapter 33 are used to estimate the loading dose. The lidocaine target MTC (C_0) = 5 mg/L, $\tau_{1/2} = 1.8$ h, $V_d = 1.1$ L/kg, and remember that $f = 1.0$ because lidocaine is administered intravenously.

$$D_0 = \frac{C_0 \times V_d}{f} \qquad (33A\text{-}3)$$

Or

$$D_0 = 5.5\,mg/kg$$

The dose of lidocaine for a 70-kg patient is therefore 5.5 mg/kg × 70 kg = 385 mg per half-life.

Calculating the Maintenance Lidocaine Dose

Equation (33A-3) predicts only how much drug to administer to achieve a specific concentration. It does not predict how much drug is needed to maintain that peak concentration. Remember the simple rule identified earlier: *replace the drug eliminated by each past half-life.* If 385 mg was administered as a loading dose, then 190 mg is required each half-life (1.8 hours) to replace the drug that is eliminated during that half-life. Lidocaine is usually infused intravenously to maintain a concentration near 5 mg/L. An infusion of 1.75 mg/min (190 mg/1.8 hr) would be indicated based on this logic.

However, this patient is on phenobarbital, which induces cytochrome CyP 2D6, which increases the rate of lidocaine metabolism. There are no quantitative indicators to predict exactly how much affect phenobarbital has on lidocaine metabolism. Empirically, it is likely that the half-life will change by 30% from 1.8 to 1.2 hours. Such an assumption would indicate that the infusion should be increased to 2.6 mg/min (190 mg/1.2 hr). Check the lidocaine concentration five half-lives (6 hours) later to confirm that the assumptions used in the calculation of dose were correct, and adjust the dose based on the reported concentration.

Estimation of the Procainamide Dose

Again, use equation (33A-3) and data from Table 33-2 of the textbook version of this chapter: normally, $C_0 = 10$ mg/L, $\tau = 6$ h, $V_d = 1.9$ L/kg, and $f = 0.83$ for oral administration.

$$D_0 = \frac{C_0 \times V_d}{f} \qquad (33A\text{-}3)$$

thus

$$D_0 = (10\,mg/L \times 1.9\,L/kg)/0.83 = 22.9\,mg/kg$$

The dose for a 70-kg patient would be 22.9 mg/kg × 70 kg = 1603 mg per half-life. Remembering to replace the amount of drug eliminated by each past half-life, the maintenance dose would be 1603 mg × 0.5 = 802 mg administered once each half-life. Conveniently, there is a

Continued.

CASE STUDY 2—cont'd

proprietary product available to deliver 750 mg of procainamide, which should provide an appropriate dose if administered once every 6 hours.

The fact that both procainamide and NAPA are low (5 μg/mL with a reference interval of 8 to 16 μg/mL), and that they are approximately the same (i.e., this patient is not phenotypically a fast metabolizer), indicates that both procainamide and NAPA are undergoing enhanced metabolism. Why? Because phenobarbital induces procainamide and NAPA metabolism. Use the same logic as applied to lidocaine to correct for this.

Practical note: All calculated results described in this case study are based on empirical estimates. After five half-lives, measure the lidocaine or procainamide concentration in the blood and make adjustments in dose to account for real variances that occur from patient to patient.

CASE STUDY 3

Presentation

A 72-year-old man weighing 60 kg has undergone surgery for repair of a heart valve. He has had prolonged disease that has caused poor blood flow, which has damaged his kidneys. At the time of surgery, his renal clearance is 50 mL/min. One day after surgery, his fever spikes to 38.5 °C. Blood cultures reveal a systemic infection by *Staphylococcus aureus.* Sensitivity testing indicates that a minimal inhibitory concentration (MIC) of vancomycin of 15 μg/mL will be required to kill the organism. What loading and maintenance doses of vancomycin should you administer? What trough concentration would you predict for this maintenance dose?

Resolution

Resolution of this case will require the calculation of the loading dose of vancomycin and predicting the trough concentration of the drug.

Calculating the Loading Dose

The approach described previously using equation 33A-3 and data from Table 33-5 of Chapter 33 allows for a simple and direct approach to calculating loading dose. Key data include $C_0 = 30$ mg/L, $\tau_{1/2} = 6$ h, and $V_d = 0.5$ L/kg; remember that $f = 1.0$ because vancomycin is administered intravenously.

$$D_0 = \frac{C_0 \times V_d}{f} \qquad (33A\text{-}3)$$

thus

$$D_0 = 15 \text{ mg/kg}$$

Therefore the initial loading dose for a 60-kg patient is 15 mg/kg × 60 kg = 900 mg.

Infusion of vancomycin is usually carried out over a period of 1 hour, and like most antibiotics, it is not administered once every half-life like the other drugs discussed in these problems. Recall that antibiotics are administered to achieve a concentration above the MIC, and then allowed to be eliminated to protect sensitive organs (kidney and 7th vestibular nerve). Therefore the general rule used in the other case studies to replace the drug lost each half-life does not apply here. Antibiotics are usually administered no more than once every other half-life and frequently less often.

This patient has significantly reduced renal function, which affects vancomycin clearance. Data listed in Tables 33-5, 33-6, and 33-7 of Chapter 33 can be used to adjust the dosage to compensate for renal clearance. The PDR also contains a nomogram for dosage adjustment that provides similar guidance to that contained in Tables 33-5, 33-6, and 33-7. These nomograms suggest that a reduced dose could be administered every 12 hours, or the full dose could be introduced every 24 hours.

Equation 33A-4 can be used to predict the actual half-life in this patient; define the targets as $C_0 = 30$ mg/L, $D_0 = 900$ mg, and $Cl = 50$ mL/min:

$$C_0 = \frac{D_0 \times f}{Cl_T \times \tau} \qquad (33A\text{-}4)$$

Rearranging equation (33A-4) gives

$$\tau = \frac{D_0 \times f}{Cl_T \times C_0}$$

thus

$$\tau_{1/2} = 600 \text{ min } (10 \text{ hr})$$

In this particular case, the physician is likely to choose to administer the dose calculated above once per day (instead of twice per day, as would be the norm) to compensate for renal function. Note that the data obtained from Table 33-7 and the PDR, and derived using equation 33A-4, lead to the same conclusion.

What Is the Predicted Trough Concentration?

The blood concentration can be estimated at any time during the elimination time interval using equation 33A-5

$$\ln C_t = \ln C_0 - k_t \qquad (33A\text{-}5)$$

or the combination of equations (33A-1) and (33A-2). Note that the combination of equations (33A-1) and (33A-2), which incorporates the variable half-life that we are concerned about in this problem, offers us more flexibility to predict trough concentration at the end of 24 hours ($\tau_{1/2} = 24$ hr) using the data defined previously (remember, we have estimated that $\tau_{1/2} = 10$ hr). Thus:

$$k = 0.0693 \text{h}^{-1} \text{ and } \quad C_{24h} = 11.4 \text{ mg/L}$$

This calculated trough concentration is slightly high for organ safety (see Table 33-6). If this calculated concentration is corroborated by measurement of an actual serum concentration, it indicates that the dose should be reduce slightly (~10%). It is common practice to measure the peak and trough concentration after the second dose is administered to verify that the assumptions made in calculating the dose are correct. With knowledge of the peak and trough

CASE STUDY 3—cont'd

concentration, the actual half-life can be calculated, and changes in dosing or dose interval can be quickly implemented.

Practical note: All estimated results described in this case study are based on assumptions. Measure the drug concentration in the blood serum and make adjustments in dose to account for the real variances in pharmacokinetic values that occur from patient to patient. Remember that the pharmacokinetic data presented in the tables of this chapter represent average data from a large number of patients; individual patients will vary from these averages. In practice, pharmacokinetic data should always be individualized for *the patient.*

METHOD 34-1 Determination of Acetaminophen

Acetaminophen is a commonly used analgesic and antipyretic agent. When taken in an overdose, acetaminophen may cause serious hepatotoxicity. Whereas acetaminophen is detected in the popular Toxi-Lab thin-layer chromatography (TLC) procedure, it is not detected in some other TLC procedures, and it generally demonstrates poor gas chromatographic properties unless derivatized. Therefore a relatively rapid screening procedure for acetaminophen in urine is clinically useful. A gold particle lateral flow qualitative immunoassay for acetaminophen (cutoff, 25 μg/mL) in serum, plasma, or whole blood has been developed (SureStep, Applied Biotech, San Diego). However, a quantitative method is typically used in any patient with suspected drug toxicity.

Reagents

1. Saturated o-cresol. Mix 10 mL of o-cresol with 1 L of deionized water. Allow to stand for 24 hours before use. Solution will be stable for 1 year at room temperature.
2. Ammonium hydroxide, 4 mol/L. Dilute 284 mL of concentrated ammonium hydroxide to 1 L with deionized water. Solution will be stable for 1 year at room temperature.
3. Concentrated hydrochloric acid.

Procedure

1. Mix 1 mL of the specimen (patient or control urine and water blank) and 1 mL of concentrated hydrochloric acid. Heat at 100 °C for 10 minutes.
2. Cool and add 100 μL of the above solution to 10 mL of o-cresol reagent and then 2 mL of ammonium hydroxide, 4 mol/L.

Acetaminophen is hydrolyzed to p-aminophenol, which reacts with o-cresol and ammonium hydroxide to form an iodophenol blue chromogen.

METHOD 34-2 Determination of Salicylate

Salicylate, the major metabolite of aspirin, is not normally detected by TLC, and its gas chromatographic response is variable without derivatization. Therefore a spot test, which may be applied at the point of care, is useful to screen for the possible presence of salicylates. A rapid gold particle lateral flow qualitative immunoassay for salicylate (cutoff, 10 mg/dL) in serum and plasma has been developed (SureStep, Applied Biotech, San Diego). Quantitative procedures for salicylate determination are discussed in Chapter 34 and typically used in any case of suspected drug overdose.

Reagent

Trinder's reagent. Dissolve 4 g of mercuric chloride in about 85 mL of deionized water by stirring on a hot plate (60 °C). Cool the solution and add 12 mL of 1 mol/L hydrogen chloride and 4 g of ferric nitrate and stir. When dissolved, transfer the solution to a 100-mL volumetric flask and dilute to volume with deionized water. Solution will be stable for 1 year at room temperature.

Procedure

Pipette 100 μL of the patient's serum or urine and control serum or urine into respective wells of a white porcelain spot plate. Add 100 μL of Trinder's reagent to each well and swirl to mix. The immediate development of a violet color indicates the possible presence of salicylates. Diflunisal and labetalol will produce a positive test response.

METHOD 34-3 Determination of Phenothiazines

The phenothiazines constitute a rather large group of widely prescribed drugs with antipsychotic pharmacological action. These drugs have a very high therapeutic index. Nevertheless, life-threatening intoxication (coma and respiratory depression) can result from an overdose with phenothiazines. A rapid spot test may be beneficial for the assessment of possible phenothiazine overdose. Phenothiazines are extensively metabolized to a large number of metabolites. The presence of these metabolites may lead to some confusion when interpreting thin-layer chromatograms.

The ferric chloride, perchloric acid, and nitric acid (FPN) spot test may be helpful when used in conjunction with TLC screening. The phenothiazines are discussed in Chapter 34.

Reagent

FPN reagent. Mix 5 mL of ferric chloride (50 g/L), 45 mL of perchloric acid (200 mL/L), and 50 mL of nitric acid (500 mL/L). The reagent is stable for 6 months when stored in a brown bottle at room temperature.

Procedure

Place 200 μL of unknown and control urine into respective wells of a white porcelain spot test plate. Add 200 μL of FPN reagent and rotate the plate to mix. A pink, red, purple, or blue color that forms immediately suggests the presence of phenothiazines. Disregard any color formation that occurs after 10 seconds. Not all phenothiazines produce a positive test result.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 34-4 Determination of Ethchlorvynol

Ethchlorvynol is a sedative hypnotic drug that is similar in action to barbiturates. In overdose, ethchlorvynol may produce deep coma that lasts several days, severe respiratory depression, hypotension, bradycardia, and death. Ethchlorvynol is not detected with some TLC procedures. When detected, ethchlorvynol may not be completely resolved from glutethimide. Thus a color test for ethchlorvynol is useful in conjunction with TLC.

Reagents

1. Color reagent. Dissolve 0.2 g diphenylamine in 50 mL of concentrated sulfuric acid. Carefully add this solution, while stirring, to 50 mL of deionized water.
2. Trichloroacetic acid (10 g/dL).

Procedure

1. Add 50 µL of the patient's serum or urine and control serum or urine to respective 3-mL test tubes.
2. Add 400 µL of trichloroacetic acid reagent. Mix and let stand for 10 minutes. May omit incubation for urine.
3. Centrifuge and transfer clear supernatant to a 3-mL test tube. May omit this step when the specimen is urine.
4. Add 300 µL of color reagent. Mix and let stand for 5 minutes.
5. Add 300 µL of chloroform and mix in a vortex mixer.
6. Centrifuge for 1 minute to separate layers.

The presence of a pink color in the chloroform layer (bottom) indicates a positive test result for ethchlorvynol. Phenothiazines may produce a light pink color that fades and cannot be extracted into chloroform.

METHOD 34-5 Determination of Drugs Using Gas Chromatographic Analysis With Flame Ionization Detection

Principle

Significant concentrations of many drugs are extracted from physiological fluids (e.g., serum, urine, and gastric fluid) at pH 4.0 into a mixed organic phase (chloroform:ethyl acetate, 8:2 vol/vol). The organic phase is separated, removed, dehydrated with anhydrous sodium sulfate, and evaporated. The residue is dissolved in 100 µL of methanol, and an aliquot is analyzed by capillary column gas chromatography (GC).

Specimens

Two milliliters of a random urine sample, 2 mL of serum, or 0.5 mL of gastric fluid is a suitable specimen. Refrigerate specimens if a delay of more than a few hours is likely before delivery to the laboratory. Do not use acetic acid or toluene as a preservative for urine.

Equipment

A gas chromatograph equipped with a capillary column, flame ionization detector, temperature programming, and splitless sample injection is used for analysis. A fused silica capillary column (15 m × 0.31 mm internal diameter [I.D.] DB-5 [bonded SE-54], J & W Scientific, Folsom, CA.) is used with helium carrier gas (80 cm/s). Conditions of operation are injector, 250 °C; detector, 325 °C; oven, initially 80 °C (0.4 minute); 30 °C/min to 140 °C (1 minute); 5 °C/min to 190 °C; 15 °C/min to 320 °C (5.1 minutes).

Reagents

1. Stock reference solutions.
   a. Group A solutions. Prepare individual reference solutions at a final concentration of 1 mg/mL of each of the following drugs by transferring 10 mg (correct for salt) of a drug into a 10-mL volumetric flask, dissolving the drug in ethanol, and diluting to volume with ethanol. These stock reference solutions are stable for 3 years if stored at −20 °C in a tightly sealed glass volumetric flask. The drugs in group A are diazepam, flurazepam, imipramine, phencyclidine (PCP), propoxyphene, and thioridazine.
   b. Group B solutions. Prepare individual reference solutions at a final concentration of 5 mg/mL of each of the following drugs by transferring 50 mg of the drug into a 10-mL volumetric flask, dissolving the drug in ethanol, and diluting to volume with ethanol. These stock reference solutions are stable for 3 years if stored at −20 °C in a tightly sealed glass volumetric flask. The drugs in group B are amobarbital, butalbital, glutethimide, ibuprofen, meprobamate, methyprylon, methaqualone, pentobarbital, phenobarbital, and phenytoin.
   c. Group C solutions. Prepare individual reference solutions at a final concentration of 25 mg/mL by transferring 250 mg of each drug into a 10-mL volumetric flask, dissolving the drug in ethanol, and diluting to volume with ethanol. These reference solutions are stable for 3 years if stored at −20 °C in a tightly sealed glass volumetric flask. The drugs in group C are acetaminophen and salicylate.
   d. Group D solutions. Drugs that are less stable or require different preparation from those in groups A, B, and C are in this group. They are prepared as follows:
      (1) Ethchlorvynol, 10.0 mg/mL. Dissolve 100 mg of ethchlorvynol in 5 mL of ethanol, place in a 10-mL volumetric flask, and dilute to final volume. The solution is stable for 1 year if stored at −20 °C in a tightly sealed container.
      (2) Chlordiazepoxide, 1 mg/mL. Dissolve 10 mg of chlordiazepoxide in ethanol in a 10-mL volumetric flask and dilute to volume. The solution is stable for 1 year if stored at −20 °C in a tightly sealed container. Avoid exposure to fluorescent lights.
      (3) Caffeine, 10 mg/mL. Place 100 mg of caffeine in a 10-mL volumetric flask and dissolve in 5 mL of water. When completely dissolved, dilute to volume with ethanol. The solution is stable for 3 years if stored at −20 °C in a tightly sealed container.
      (4) Mephobarbital, 1 mg/mL. Place 10 mg of mephobarbital in a 10-mL volumetric flask, dissolve, and dilute to volume with ethanol. The solution is stable for 3 years if stored at −20 °C in a sealed flask.
2. Combined drug calibrator. Prepare as follows in a 500-mL volumetric flask:

Continued.

METHOD 34-5 Determination of Drugs Using Gas Chromatographic Analysis With Flame Ionization Detection—cont'd

Drug or Group	Volume	Final Concentration of Each Drug
A	1.0 mL each	2.0 μg/mL
B	1.0 mL each	10.0 μg/mL
C	1.0 mL each	50.0 μg/mL
Ethchlorvynol	2.5 mL	50.0 μg/mL
Chlordiazepoxide	5.0 mL	10.0 μg/mL
Caffeine	0.5 mL	10.0 μg/mL
Mephobarbital	2.5 mL	5.0 μg/mL

Add 100 mL of sterile bovine serum, dilute to final volume with deionized water, and mix thoroughly. This calibrator is to be analyzed on 3 separate days and must agree within ±20% of the spiked values. It is then aliquoted and stored at −20 °C and is stable for 1 year. The final concentration of each drug is as follows:

Acetaminophen, 50 μg/mL
Amobarbital, 10 μg/mL
Butalbital, 10 μg/mL
Caffeine, 10 μg/mL
Chlordiazepoxide, 10 μg/mL
Diazepam, 2 μg/mL
Ethchlorvynol, 50 μg/mL
Flurazepam, 2 μg/mL
Glutethimide, 10 μg/mL
Ibuprofen, 10 μg/mL
Imipramine, 2 μg/mL
Mephobarbital, 5 μg/mL
Meprobamate, 10 μg/mL
Methyprylon, 10 μg/mL
Methaqualone, 10 μg/mL
Pentobarbital, 10 μg/mL
Phenobarbital, 10 μg/mL
Phencyclidine, 2 μg/mL
Phenytoin, 10 μg/mL
Propoxyphene, 2 μg/mL
Salicylate, 50 μg/mL
Thioridazine, 2 μg/mL

3. Control pool. Prepare a control pool for daily use by adding the following to a 500-mL volumetric flask: 0.5 mL of 1-mg/mL imipramine, 1.5 mL of 1-mg/mL mephobarbital, 2.0 mL of 5-mg/mL pentobarbital, and 1.0 mL of 1-mg/mL thioridazine. Add 100 mL of bovine serum and dilute to a final volume of 500 mL with deionized water. The final concentration will be 1 μg/mL of imipramine, 3 μg/mL of mephobarbital, 20 μg/mL of pentobarbital, and 2 μg/mL of thioridazine. The pool should be analyzed on 5 separate days to establish mean and standard deviation and should be within ±20% of the spiked values. This reagent is stable for 1 year at −20 °C.
4. Internal standard (0.2 mg/mL benzocaine and 0.2 mg/mL cyheptamide). Transfer 20 mg of benzocaine and 20 mg of cyheptamide into a 100-mL volumetric flask and dissolve in 100 mL of ethanol. This reagent is stable for at least 1 year if stored at 4 °C in a sealed container.
5. Acetic acid, 1.0 mol/L. Carefully, and with continuous mixing, add 57.3 mL of concentrated acetic acid to approximately 800 mL of distilled water in a 1-L volumetric flask. Cool to room temperature, dilute to volume with distilled water, and mix thoroughly.
6. Sodium acetate, 1.0 mol/L, pH 4.0. Carefully add 57.3 mL of concentrated acetic acid to 800 mL of water as in step 4. Titrate the mixture to pH 4.0 by the dropwise addition of 10 mol/L of sodium hydroxide carefully (wear protective eyewear). Let the solution cool to room temperature and dilute to final volume of 1 L with water.
7. Anhydrous sodium sulfate, American Chemical Society (ACS) grade.
8. Extraction solvent. Mix 100 mL of chromatographic grade ethyl acetate with 400 mL of chromatographic grade chloroform. Store in sealed glass pipettor bottle.
9. Methanol, chromatographic grade.

Procedure

1. Label one 16 × 125-mm disposable glass test tube for each calibrator, control, or unknown.
2. Prepare calibrators or specimens as follows:
   a. Calibrator: Combine 2.0 mL of combined drug calibrator; 1.0 mL of 1 mol/L sodium acetate (NaOAc), pH 4.0; 100 μL internal standard; and 6 mL of extraction solvent.
   b. Serum: Combine 2.0 mL of serum, 1.0 mL of 1 mol/L acetic acid, 100 μL internal standard, and 6 mL of extraction solvent. If less than 2.0 mL of serum is available, make up to a volume of 2.0 mL with water, and use sodium acetate buffer instead of acetic acid. Apply the appropriate multiplication factor to correct for dilution.
   c. Urine: Combine 2.0 mL of urine, 1.0 mL of 1 mol/L NaOAc, 100 μL internal standard, and 6 mL of extraction solvent.
   d. Gastric fluid: Add 0.5 mL of gastric specimen to 1.5 mL of water; 1.0 mL 1 mol/L NaOAc, pH 4.0; 100 μL internal standard; and 6 mL of extraction solvent.
3. Using a vortex mixer, mix thoroughly for 30 seconds and centrifuge for 3 minutes. (If an emulsion forms, stir the solution with a wooden dowel and recentrifuge for 3 minutes.)
4. Transfer approximately 5 mL of the organic solvent to a 12 × 125-mm disposable glass test tube and add one scoop (0.5 g) of anhydrous sodium sulfate. Mix in a vortex mixer for 5 to 10 seconds, then decant the organic phase to a clean glass conical tip tube.
5. Evaporate the ethyl acetate/chloroform retraction solvent under a gentle stream of nitrogen with gentle heating (i.e., temperature no higher than 40 °C). Avoid overdrying the specimen (do not allow it to sit for a prolonged period of time in the evaporation apparatus with nitrogen flush after the specimen has dried). Overdrying causes degradation of benzocaine and evaporation of ethchlorvynol.
6. Redissolve the residue in 100 μL of methanol and mix thoroughly. Inject an aliquot into the gas chromatograph.

Interpretation

Drugs in the unknown specimen are identified by comparison of the retention time for any peaks present with those of the reference drugs (±0.05 minute) (Figure A34-1). Quantitation for drugs identified in serum is performed by a comparison of the peak height ratio (drug:cyheptamide) with that for the calibrator:

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 34-5 Determination of Drugs Using Gas Chromatographic Analysis With Flame Ionization Detection—cont'd

$$\text{Concentration} = \frac{R_u}{R_c} \times C_c$$

where
R_u = Peak height ratio for the unknown
R_c = Peak height ratio for the calibrator
C_c = Concentration of the calibrator

The second internal standard, benzocaine, is used to monitor loss of ethchlorvynol, ibuprofen, and salicylate during the drying step. If a low response for benzocaine is observed, the specimen should be reextracted and more carefully dried to prevent total dehydration of the extract, which destabilizes these drugs.

METHOD 34-6 Determination of Carbon Monoxide by Spectrophotometry

Principle

Hemoglobin and its derivatives have characteristic absorption bands in the visible light region that can be used to measure the carboxyhemoglobin level. Oxyhemoglobin and carboxyhemoglobin have similar double bands in alkaline solution. The absorption maxima for oxyhemoglobin are 576 to 578 and 540 to 542 nm; for carboxyhemoglobin, they are 568 to 572, and 538 to 540 nm (Figure A34-2). Deoxyhemoglobin has a single broad band at 555 nm (see Figure A34-2, *B* and *C*).

If a weak alkaline dilution of blood is treated with sodium hydrosulfite, oxyhemoglobin (and any methemoglobin present) is converted to deoxygenated hemoglobin (see Figure A34-2). Carboxyhemoglobin is unaffected by such treatment (see Figure A34-2, *D*).

$$HbO_2 \text{ (or MetHb)} + Na_2S_2O_4 \rightarrow Hb$$

$$HbCO + Na_2S_2O_4 \rightarrow \text{No reaction}$$

The absorbance of this solution is measured at 541 and 555 nm, the absorbance ratio A_{541}/A_{555} is calculated, and the percent carboxyhemoglobin is determined from the calibration curve.

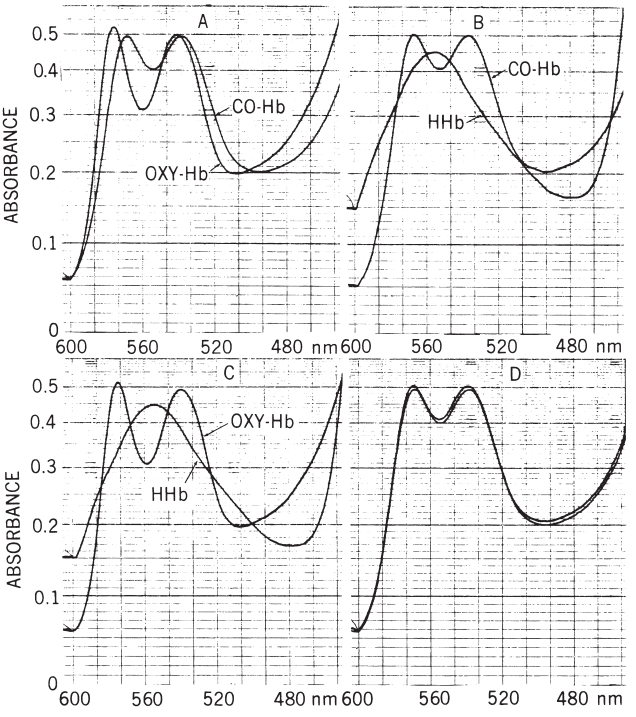

Figure A34-2 Spectral curves (over traced). **A,** 100% oxyhemoglobin (OXY-Hb) and 100% carboxyhemoglobin (CO-Hb) before treatment with sodium dithionite. **B,** 100% oxyhemoglobin (now HHb) and 100% carboxyhemoglobin after treatment of both with sodium dithionite. **C,** 100% oxyhemoglobin before and after treatment with sodium dithionite. **D,** 100% carboxyhemoglobin before and after treatment with sodium dithionite. *(Reproduced by permission of the Institute for Clinical Science; from Tietz NW, Fiereck EA. The spectrometric measurement of carboxyhemoglobin. Ann Clin Lab Sci 1973;3:36-42.)*

Instrumentation

A narrow-bandpass (<2 nm) spectrophotometer with 10-mm cuvets is required, and the use of a recording spectrophotometer with the same specifications is desirable.

It is imperative that the spectrophotometer be checked regularly for wavelength and spectrophotometric accuracy with appropriate calibrating filters (e.g., National Institute of Standards and Technology (NIST) Reference Material 930) and with liquid photometric reference materials (e.g., NIST Reference Material 931).

Reagents

1. Ammonium hydroxide, 0.12 mol/L. Dilute 15.9 mL of concentrated ammonium hydroxide to 1.0 L with deionized water. This solution is stable for 1 year.
2. Sodium hydrosulfide (sodium dithionite), reagent grade. Preweigh 10-mg portions of sodium dithionite into individual small test tubes. Stopper the test tubes or cover with Parafilm.
3. Carbon monoxide. Lecture bottle (available from Matheson Gas Products, Division of Will Ross, Inc., East Rutherford, NJ.).
4. Oxygen, chemically pure.

Procedure

1. Add 100 µL of whole heparinized blood to 25 mL of ammonium hydroxide, 0.12 mol/L. Mix the solution and allow it to stand for 2 minutes. This is the hemolysate.
2. Transfer 3.0 mL of ammonium hydroxide and 3.0 mL of the hemolysate into separate 10-mm cuvets. (Analyze the specimen in triplicate.)
3. Add 10 mg of sodium dithionite to all cuvets. Cover the cuvets with Parafilm and invert gently 10 times. If a number of hemolysates are analyzed, space the addition of the reducing agent so that each can be read after exactly 5 minutes.
4. Exactly 5 minutes after the addition of sodium dithionite to the hemolysates, read the absorbance at 541 and 555 nm against the ammonium hydroxide blank.
5. Calculate the ratio of the absorbance at 541 nm to that at 555 nm, A_{541}/A_{555}, and determine the percent carboxyhemoglobin from the calibration curve. Note: For confirmation and for the purpose of record, the specimen without and that with sodium dithionite (steps 1 and 3, respectively) may be scanned between 450 and 600 nm (see Figure A34-2).

Preparation of the Calibration Curve

Caution: Use a fume hood when working with carbon monoxide gas.

1. Collect 20 mL of heparinized blood from a healthy person who does not smoke.
2. Transfer a 4.0-mL portion of the fresh, heparinized blood specimen into each of two 125-mL separatory funnels. While the funnels are gently rotated, allow pure oxygen to flow through one funnel and pure carbon monoxide through the other for 15 minutes. After the addition of the gases, close the separatory funnels and rotate them gently for an additional 15 minutes. Analyze the fully saturated specimens immediately, in triplicate, according to the procedure described previously. Use these results for the establishment of the 0% and 100% carboxyhemoglobin calibration points. These specimens may not be used to establish the intermediate calibration points. Plot the ratio of the absorbance at 541 nm to that at 555 nm for the 0% and for the

METHOD 34-6 Determination of Carbon Monoxide by Spectrophotometry—cont'd

100% carboxyhemoglobin specimens and draw a line between the two points (Figure A34-3).

3. Fill the funnel containing the 100% carboxyhemoglobin specimen with nitrogen gas and rotate it for 5 minutes. Treatment with nitrogen removes the physically dissolved carbon monoxide from the specimen, but a small amount of carbon monoxide will also dissociate from hemoglobin. Determine the exact carboxyhemoglobin content of this specimen by the method described, using the calibration curve just prepared. Prepare intermediate calibrators by mixing appropriate proportions of the nitrogen-treated specimen with the oxygen-treated specimen.
4. Analyze each of the diluted blood specimens from step 3 in triplicate according to the procedure described previously.
5. Plot the calculated concentrations against the absorbance ratios obtained. These points should fall on the line drawn for the fully saturated specimens because the curve is linear over the entire range (see Figure A34-3).

METHOD 34-7 Determination of Cyanide

Principle

Measurement of cyanide (CN^-) in whole blood is performed following microdiffusion either by photometric analysis or by ion-selective electrode analysis. In the procedure described here, a sealed, two-well microdiffusion cell is used to separate hydrocyanic acid from blood by mixing a sample of whole blood with strong acid in a sealed chamber and allowing the hydrocyanic acid gas generated to be absorbed into a strong base located in another part of the sealed chamber. One well of the cell contains the blood specimen and a strong acid (unmixed until the cell is sealed), and the other well contains a strong base to absorb the hydrocyanic acid gas. After the hydrocyanic acid is collected in the aqueous base medium, pyridine, barbituric acid, and chloramine-T are added to generate a red complex, the intensity of the color of which is proportional to the concentration of CN^-. A good-quality spectrophotometer is required to measure the absorbance.

Reagents

1. Sodium hydroxide, 0.1 mol/L. Dilute 4.0 g of solid, anhydrous sodium hydroxide in water, allow to cool to room temperature, and dilute to 1 L of final volume with water.
2. Sulfuric acid, 3.6 mol/L. Dilute 10 mL of concentrated, reagent-grade sulfuric acid with water and allow to cool to room temperature, then dilute with water to a final volume of 100 mL.
3. Sodium dihydrogen phosphate, 1.0 mol/L. Add 13.8 g of sodium dihydrogen phosphate monohydrate ($NaH_2PO_4 \cdot H_2O$) to water and dilute to a final volume of 100 mL.
4. Chloramine-T, 0.25%. Add 0.25 g of chloramine-T to water and dilute to a final volume of 100 mL.
5. Color reagent. Add 2.0 g of barbituric acid; 10 mL of reagent-grade pyridine; and 2.0 mL of concentrated, reagent-grade hydrochloric acid to water and dilute to a final volume of 20 mL. Prepare this reagent weekly.
6. Stock calibrator solution. CN^-, 1 mg/mL. Add 0.25 g of potassium cyanide to 50 mL of water and add 2.0 mL of 0.5-mol/L sodium hydroxide. Dilute to a final volume of 100 mL. The solution is stable for 3 months.
7. Working calibrator, CN^-, 10 μg/mL. Dilute 1.0 mL of the stock calibrator solution to 100 mL of final volume with water. This solution is stable for 2 weeks. From this prepare calibrators for use daily at final concentrations of 0.2, 0.5, and 2.0 μg/mL in water.
8. Control. Obtain part of an outdated unit of whole blood from the blood bank. Perform CN^- test on a sample from it to ensure no contamination with CN^-. Add 0.1 mL of the stock calibrator to 99.9 mL of blood to generate a control pool with 1 μg/mL of CN^-. Aliquot this into small vials, seal, and store at –20 °C for use as a control pool.

Procedure

1. Using silicon vacuum grease, lightly grease the rim of a Conway diffusion cell. Alternatively a two-compartment bacterial agar plate can be used.
2. Add 0.5 mL of 0.1 mol/L sodium hydroxide to well 1 of the diffusion cell.
3. Add 1.0 mL of 3.6 mol/L sulfuric acid to well 2 of the diffusion cell.
4. Add 1.0 mL of calibrators (0.2, 0.5, and 2.0 μg/mL CN^-), control, or specimen to well 2 of the diffusion cell so that it does not mix

METHOD 34-7 Determination of Cyanide—cont'd

with the acid until after the cell is sealed. After sealing the cover on the diffusion cell, mix the sample thoroughly with acid by gently tilting the cell back and forth. Avoid mixing the contents of well 1 with those of well 2.

5. Let the diffusion cell stand for 2 hours at room temperature or for 15 minutes at 60 °C to allow hydrocyanic acid to diffuse out of the specimen and dissolve in the strong base.
6. Open the diffusion cell and transfer 0.2 mL of the fluid from the base side (well 1) of the cell to a 12 × 75-mm disposable test tube.
7. Add 1.0 mL of 1 mol/L sodium dihydrogen phosphate and 0.5 mL of chloramine-T, mix thoroughly, and let stand for 1 minute. Add 1.5 mL of color reagent, mix, and let stand for 10 minutes.
8. Measure the absorbance at 580 nm of each solution in a spectrophotometer, subtracting background absorbance at 480 nm. Calibrate the assay using the absorbance derived from the calibrators, and calculate the CN^- concentration in each specimen directly from the absorbance exhibited by each.

METHOD 34-8 Determination of Alcohols by Headspace Gas Chromatographic Analysis

Principle

In a closed system, short-chain aliphatic alcohols and acetone are sufficiently volatile to be present in easily measurable concentrations in the air space (headspace) above a liquid specimen. Therefore a portion of this headspace may be injected into a gas chromatograph for analysis. Headspace sampling provides an extremely clean specimen, resulting in prolonged column performance and no clogging of syringe needles.

For the analysis of alcohols in blood or serum, dilutions are made with saturated sodium chloride containing n-propanol as the internal standard. Sodium chloride increases the vapor pressure of the alcohols and eliminates matrix differences between aqueous calibrators and blood or serum specimens. For quantitation, the peak height ratio of the analyte alcohol to the internal standard is compared with the ratio for calibrators.

Instrumentation

Method requires a gas chromatograph equipped with a flame ionization detector, a fused silica capillary column (e.g., 30 m × 0.53 mm ID, 3-µm film thickness, Rtx-BACl, Restek, Bellefonte, Pa., operated at 40 °C), and a headspace sampling device.

Reagents

All reagents are anhydrous and of analytical reagent grade.

1. Combine alcohol, acetone calibrator. Dilute 2.0 mL each of anhydrous ethanol and methanol, 1.0 mL of isopropanol, and 0.25 mL of acetone to 1 L with deionized water. At 20 °C, this provides a calibrator with concentrations of: ethanol, 158 mg/dL; methanol, 157 mg/dL; isopropanol, 78 mg/dL; and acetone, 20 mg/dL. This calibrator is suitable for routine use.

   For linearity verification or for multipoint calibration, a combined stock reference solution may be prepared by diluting 6.3 mL each of ethanol and acetone and 6.4 mL each of methanol and isopropanol to 500 mL of deionized water. This stock reference solution (1000 mg/dL for both ethanol and isopropanol, 1006 mg/dL for methanol, and 1008 mg/dL for acetone) may be appropriately diluted to provide concentrations of each analyte from 25 mg/dL to ~600 mg/dL.
2. Internal standard solution. Dilute 0.5 mL of n-propanol to 1 L with deionized water saturated with sodium chloride.

Procedure

1. Place 50 µL of each calibrator, control, or patient's specimen into a 20-mL headspace vial.
2. Add 200 µL of internal standard solution.
3. Seal the vial and swirl to mix contents.
4. Place vials into a sampling turntable; incubate at 40 °C for 3 minutes before injecting the headspace specimen into a gas chromatograph.

Calculation

Calculate the ratio of the peak height (or peak area) of the unknown to that of the internal standard, n-propanol. Compare this ratio with the ratios obtained for the corresponding calibrators. A typical chromatogram is shown in Figure A34-4.

METHOD 34-9 Determination of Formate by Gas Chromatographic Analysis

Principle

Formate, present in serum or whole blood, and propionate, added as an internal standard, are converted to their respective methyl esters in the presence of sulfuric acid and excess methanol. For quantitation, the peak height ratio of methyl formate to methyl propionate for the unknown, measured by headspace gas chromatography, is compared with the ratios for known calibrators.

Instrumentation

A gas chromatograph equipped with a column containing 5% Hallcomid M-18 and 0.5% Carbowax 600 coated on 40-60 mesh Teflon-6, operated at 75 °C, and a flame ionization detector are required for analysis.

Reagents

1. Formate reference solution. Dissolve 1.481 g of sodium formate in 100 mL of deionized water. This provides a stock reference solution equivalent to 1.0 g/dL as formic acid. Make appropriate dilutions to provide working calibrators of 20, 40, 60, 80, and 100 mg/dL formate as formic acid.
2. Internal standard. Dissolve 0.52 g of sodium propionate in 100 mL of methanol (400 mg/dL as propionic acid).

Procedure

1. Transfer 100 µL of serum, whole blood, or calibrator to a 7.5-mL vial.
2. Add 100 µL of internal standard.
3. Add 100 µL of concentrated sulfuric acid.
4. Cap the vials and place in a water bath at 35 °C for 30 minutes.
5. Inject 0.5 mL of headspace from each vial into the gas chromatograph.
6. Measure peak height ratios of methyl formate relative to that of methyl propionate. Determine the concentration of formate (as formic acid) in the unknown by comparing its peak height ratio with those ratios obtained using the calibrators.

Analyte	Relative Retention Time
Methyl formate	0.34
Methanol	1.00
Methylpropionate	1.55

METHOD 34-10 Determination of Acetaminophen by High-Performance Liquid Chromatography

Principle

Acetaminophen and 3-acetamidophenol, added as an internal standard, are extracted from serum and analyzed by reverse-phase high-performance liquid chromatography (HPLC) with an octadecylsilane bonded-phase column. The peak height absorbance ratio for acetaminophen relative to the internal standard is determined at 254 nm.

Instrumentation

A 250 × 4.5-mm ID column containing octadecylsilane (C18) bonded-silica particles (5-µm diameter) is used for the analysis of acetaminophen. The HPLC system is equipped with a fixed-(254-nm) or variable-wavelength detector set at a sensitivity of 0.1 or 0.2 absorbance units full scale for acetaminophen concentrations of 0 to 200 or 200 to 500 µg/mL, respectively. The pump flow rate is 1.5 mL/min.

Reagents

1. Acetaminophen stock reference solution, 1000 mg/L. Dissolve 100 mg of acetaminophen (USP reference material or equivalent) in 20 mL of methanol and then dilute to 100 mL with deionized water. The solution is stable for at least 6 months when stored refrigerated.
2. Acetaminophen working calibrator. Dilute the acetaminophen stock reference solution with deionized water to provide working calibrators of 20 and 100 µg/mL. Calibrators are stable for 2 months when stored refrigerated.
3. 3-Acetamidophenol stock internal standard, 1000 mg/L. Dissolve 100 mg of 3-acetamidophenol (Sigma-Aldrich, St. Louis) in 20 mL of methanol and dilute to 100 mL with deionized water. The solution is stable for 6 months when stored refrigerated.
4. 3-Acetamidophenol working internal standard, 50 mg/mL. Dilute 5 mL of the stock internal standard to 100 mL with deionized water. The solution is stable for 2 months when stored refrigerated.
5. Phosphate buffer, 0.225 mol/L, pH 7.4. Mix 80.4 mL of disodium hydrogen phosphate (Na_2HPO_4) solution (30.6 g/L) with 19.6 mL of potassium dihydrogen phosphate (KH_2PO_4) solution (31.9 g/L). Adjust to pH 7.4, if necessary, with the appropriate phosphate solution. The solution is stable for 2 months when stored at room temperature.
6. Mobile phase: sodium acetate buffer/acetonitrile (92/8 by volume). Add 80 mL of acetonitrile (HPLC-grade) to a 1-L volumetric flask and dilute to volume with 0.01 mol/L of sodium acetate buffer, pH 4.0. Filter through a 0.5-µm pore-size filter and degas by applying gentle vacuum.

Procedure

1. Pipette 100 µL of each calibrator, control, and patient's serum into properly labeled 13 × 100-mm glass tubes.
2. Add 100 µL of working internal standard solution and 100 µL of phosphate buffer (0.225 mol/L, pH 7.4). Mix.
3. Add 3 mL of ethyl acetate. Mix in a vortex mixer for 15 seconds.
4. Centrifuge all tubes at 1000 × *g* for 5 minutes.

Continued.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 34-10 Determination of Acetaminophen by High-Performance Liquid Chromatography—cont'd

5. Transfer the organic (top) layer to labeled 12 × 75-mm glass tubes and evaporate under a stream of dry air at 50 °C.
6. Reconstitute the contents of each tube with 100 µL of the mobile phase and inject 10 to 20 µL into the HPLC instrument.

Calculation

A typical chromatogram is shown in Figure A34-5. Determine the peak height (or peak area) ratios of acetaminophen relative to the internal standard. Calculate the concentration of acetaminophen in the unknown by comparing its peak height ratio with the peak height ratios versus the acetaminophen concentration response for the calibrator.

METHOD 34-11 Trinder's Method for the Determination of Salicylate

Principle

Salicylate reacts with Fe^{3+} in an acid medium to form a colored complex that is measured at 540 nm (Figure A34-6). Mercuric chloride, present in the reagent, causes precipitation of serum proteins and thus eliminates the necessity for a serum blank.

Instrument

A spectrophotometer with a bandpass of ≤20 nm at 540 nm is required.

Specimen

Serum is preferred, but plasma may be used (ethylenediaminetetraacetic acid [EDTA]), heparin, or oxalate are acceptable for use as anticoagulants).

Reagents

1. Trinder's reagent. Ferric nitrate ($Fe[NO_3]_3$), 100 mmol/L; mercuric chloride, 80 mmol/L; and hydrogen chloride, 120 mmol/L. Dissolve 40 g of mercuric chloride ($HgCl_2$) in about 600 mL of hot deionized water while stirring. Allow to cool and then add 40 g of $Fe(NO_3)_3 \cdot 9\ H_2O$ and 120 mL of 1 mol/L HCl while stirring. Transfer the solution to a 1-L volumetric flask and dilute to volume with deionized water. This solution is stable for at least 1 year at room temperature.
2. Salicylate stock reference solution, 2 g/L. Dissolve 580 mg of sodium salicylate in about 200 mL of deionized water in a 250-mL volumetric flask. Add a few drops of chloroform as a preservative and dilute to volume with water. (Note: Do not use sodium azide.) This solution is stable for at least 5 months when stored at 4 °C to 10 °C in a brown bottle.
3. Salicylate working calibrators. In separate 100-mL volumetric flasks, dilute 1.0, 2.0, 5.0, 10.0, and 25.0 mL of the stock salicylate reference solution to volume with deionized water to provide working calibrators of 20, 40, 100, 200, and 500 mg/L, respectively. These calibrators may be used for establishing and periodically rechecking the method's linearity. For routine use, a single working calibrator (200 mg/L) is adequate. These calibrators, if prepared to contain a few drops of chloroform, are stable for 3 months when stored refrigerated in a brown bottle.

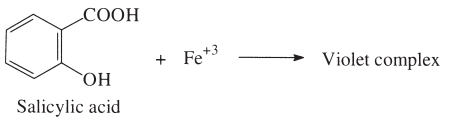

Figure A34-6 Trinder's reaction for salicylic acid.

Procedure

1. Add 100 µL of the patient's serum or the control to properly labeled 13 × 100-mm test tubes.
2. Add 100 µL of a calibrator and 100 µL of water to separate cuvets.
3. Add 1 mL of deionized water to all test tubes and to the calibrator and blank cuvets, then add 1 mL of Trinder's reagent and mix.
4. Allow the specimens to stand for 5 minutes and then centrifuge the patient's and control test tubes for 10 minutes at 1000 × *g*. Transfer the supernatants to cuvets.
5. After adjusting the spectrophotometer to zero absorbance (100% transmittance) with the reagent blank, measure the absorbance of the calibrator and that for the patient's and control specimens.

METHOD 34-11 Trinder's Method for the Determination of Salicylate—cont'd

Calculation

Calculate the concentration of salicylate by comparing the absorbance values for the unknowns with that for the calibrator:

$$\frac{A_{unknown}}{A_{cal}} \times C_{cal} = \text{salicylate, mg/L}$$

References

Trinder P. Rapid determination of salicylate in biological materials. Biochem J 1954;57:301-3.

METHOD 34-12 Determination of Salicylate and Metabolites by High-Performance Liquid Chromatography

Principle

Serum protein is first precipitated with acetonitrile, which contains o-methoxybenzoic acid as an internal standard. Salicylic acid, salicyluric acid, and gentisic acid are then separated with an octadecylsilane reverse-phase chromatographic column. Quantitation is performed by calculating the ratio of peak height absorbance (313 nm) of the analyte to that for the internal standard and then by comparing this ratio with appropriate calibrators.

Instrumentation

An HPLC equipped with an ultraviolet light detector (313 nm) and a 250 × 3.9-mm octadecylsilane column (5-μm particle size) and with a pump operated at a flow rate of 2.6 mL/min is required for analysis.

Reagents

1. Sodium azide stock solution. Dissolve 20 g of sodium azide in about 80 mL of deionized water. Adjust the pH to 7.4 with acetic acid. Transfer to a 100-mL volumetric flask and dilute to volume with deionized water.
2. Stock reference solution. Dissolve 200 mg each of salicylic acid, salicyluric acid, and gentisic acid (2,4-dihydroxybenzoic acid) in about 80 mL of deionized water, add 20 μL of stock sodium azide, and dilute to volume in a 1000-mL volumetric flask.
3. Working calibrators. Make appropriate dilutions of the stock reference solution with a solution of 100 mg/L sodium azide (pH 7.4) to provide additional calibrators of 100, 50, 25, 5, and 1 mg/L each of salicylic acid, salicyluric acid, and gentisic acid.
4. Internal standard. Dissolve 20 mg of o-methoxybenzoic acid in 100 mL of acetonitrile. Dilute this solution tenfold with acetonitrile to provide a final o-methoxybenzoic acid concentration of 20 mg/L.
5. Mobile phase. Combine 41 mL of glacial acetic acid and 180 mL of methanol in a 1 L volumetric flask and dilute to volume with deionized water.

Procedure

1. Add 100 μL of the patient's serum, calibrators, or control to properly labeled 10 × 70-mm test tubes.
2. Add 100 μL of internal standard solution; mix in a vortex mixer for 1 minute.
3. Centrifuge at 900 × *g* for 10 minutes. Inject 20 μL of supernatant onto the HPLC column.

Calculation

Prepare a calibration curve by plotting the peak height absorbance ratio (peak height calibrator:peak height internal standard) versus the concentration of the calibrators. Calculate the peak height ratio for the unknown and determine the corresponding concentration from the respective calibration curve.

Approximate retention times are as follows: gentisic acid, 3.7 minutes; salicyluric acid, 5.4 minutes; internal standard, 7.7 minutes; and salicylic acid, 11.3 minutes.

METHOD 34-13 Simultaneous Determination of Ethylene Glycol and Glycolic Acid by Gas Chromatography-Mass Spectrometry

Principle

After precipitation of serum proteins with acetonitrile (containing internal standards), the supernatant is treated with 2,2-dimethoxypropane (containing dimethylformamide) to remove water, and the volume is reduced to <100 µL of dimethylformamide.

Following addition of a derivatizing reagent, the analytes are measured as their t-butyl-dimethylsilyl derivatives by gas chromatography-mass spectrometry.

Instrumentation

A gas chromatograph equipped with a mass selective detector and a fused silica capillary column (e.g., 25 m × 0.2 mm [ID], 0.33-µm film thickness, and cross-linked 5% phenylmethyl silicon, J & W Scientific Ultra 2) is required. The instrument is operated in the selected ion-monitoring mode, and the oven temperature is programmed from 80 °C (0.5 minutes) to 325 °C at 25 °C/min.

Reagents

1. Ethylene glycol (EG)-glycolic acid (GA) stock reference solution (5.0 g/dL each). Place 2.5 g each of ethylene glycol and glycolic acid in a 50-mL volumetric flask. Dissolve in and dilute to volume with deionized water. Aliquots are stable for 12 months at −10 °C to −20 °C.
2. Calibrator (100 mg/dL each EG-GA). Place 200 µL of stock reference standard in a 10-mL volumetric flask and dilute to volume with analyte free pooled serum. This solution is stable for 6 months at −10 °C to −20 °C.
3. Internal standards. Place 15 mg each of 1,3-propanediol (1,3-PD) and α-hydroxyisobutyric acid (HIBA) and 10 mL of glacial acetic acid in a 100-mL volumetric flask. Dissolve in and dilute to volume with acetonitrile. This solution is stable for 3 months at room temperature in an amber bottle.
4. 2,2-dimethoxypropane (DMP): N,N-dimethylformamide (DMF) (80:20 vol/vol). Combine 80 mL DMP and 20 mL DMF. This solution is stable for 3 months at room temperature.
5. N-methyl-N-(tert-butyldimethylsilyl)-trifluoroacetamide (MTBSTFA; Pierce, Rockford, IL.).

Procedure

1. To tubes containing 50 µL of the patient's serum (neat and diluted 1:5 with pooled serum), pooled serum blank, control (20 mg/dL and 80 mg/dL each analyte) or calibrator, add 150 µL of internal standard solution.
2. Mix using a vortex mixer and then centrifuge 14,000 × *g* for 1 minute.
3. To 100 µL of supernatant, add 50 µL of DMP:DMF and vortex.
4. Place the tubes in an 80 °C heat block and reduce volume under air flow to <100 µL (but not to dryness).
5. Add 100 µL MTBSTFA and inject 1 µL into gas chromatography-mass spectrometry (GC-MS) operated in selected ion-monitoring mode for the following mass units: 147 and 233 (EG); 147 and 247 (1,3-PD); 147,189, and 247 (GA); 147,189, and 275 (HIBA).

Calculation

Analyte identification is based on retention time and ion ratios compared with the respective calibrator response. For EG quantitation, the ratio of 233 (EG) to 247 (1,3-PD) is compared with that for the calibrator; for GA, the ratio of 247 (GA) to 275 (HIBA) is compared similarly. A typical chromatogram is depicted in Figure A34-7.

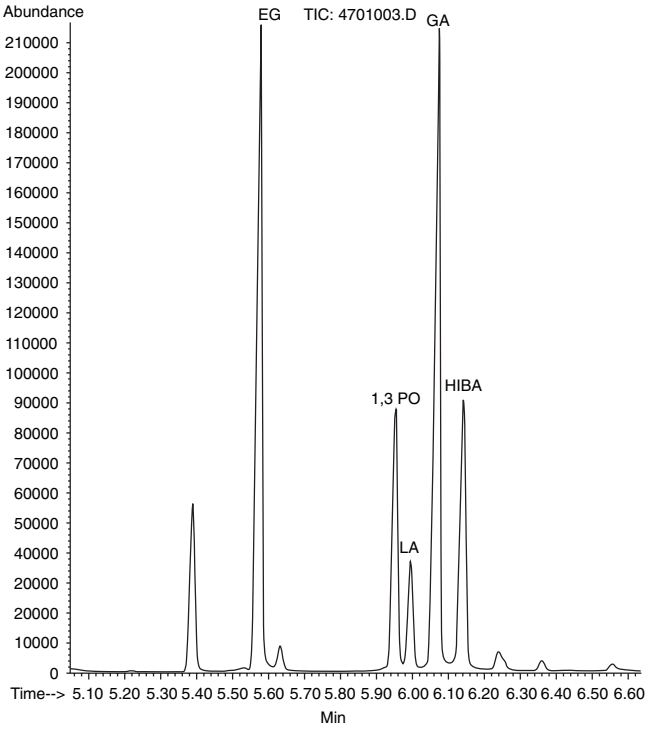

Figure A34-7 Total-ion chromatogram for ethylene glycol and glycolic acid. Ethylene glycol (EG), 1,3-propanediol internal standard (1,3-PD), endogenous lactic acid (LA), glycolic acid (GA), HIBA internal standard.

Procedure Notes

1. The procedure requires <2 hours.
2. The method is linear to 100 mg/dL of EG and GA, but is effectively extended to 500 mg/dL by automatic 1:5 dilution; higher dilutions may be made if required.
3. Single-point calibration provides accuracy and precision comparable with multiple-point calibration.
4. DMP acts as a water scavenger to convert water to methanol and acetone; DMF acts as a solvent trap during the evaporation step. Complete dryness results in loss of response.
5. The limit of detection and/or quantitation is 1 mg/dL of EG and GA.

METHOD 34-14 Determination of Amphetamine and Methamphetamine (and MDA, MDMA, MDEA) in Urine by Gas Chromatography-Mass Spectrometric Analysis

Principle

A urine specimen that has tested positive for amphetamine or methamphetamine (or methylene dioxyamphetamine [MDA], methylene dioxymethamphetamine [MDMA], and methylene dioxyethylamphetamine [MDEA]) by immunoassay is treated with periodate to remove possible interferences caused by α-hydroxyamines, such as ephedrine, pseudoephedrine, norpseudoephedrine, and phenylpropanolamine. The periodate-treated urine is extracted at alkaline pH with an organic solvent, and the isolated organic layer is reacted with 4-carbethoxyhexafluorobutyryl chloride to derivatize the amines (Figure A34-8). After addition of ethanol to destroy excess derivatizing reagent, the solvent is removed by evaporation, and the residue is dissolved in ethyl acetate and analyzed by GC-MS using selected ion monitoring. Deuterated amphetamine-D_5 and methamphetamine-D_5 are used as internal standards. Deuterated MDA-D_5, MDMA-D_5, MDEA-D_6 are used if the designer amphetamines are also included in the analysis.

Instrumentation

A GC-MS equipped with a capillary column (e.g., 25 m × 0.20 mm ID, 0.33-μm film thickness; J & W Scientific Ultra 2) is required for analysis. The operating conditions with this column for splitless sample injection are injection port, 200 °C; detector, 315 °C; initial column temperature, 120 °C (1 minute); temperature program, 25 °C/min to 270 °C.

Reagents

1. Combined stock reference solution, 1 mg/mL. Transfer 27.2 mg of (±)-amphetamine sulfate (Sigma-Aldrich, St. Louis, MO) and 24.9 mg of (+)-methamphetamine hydrochloride (Alltech-Applied Science Labs, State College, PA.) into a 20-mL volumetric flask. Dissolve in and dilute to volume with methanol.
2. Combined intermediate reference solution, 100 μg/mL. Dilute 2.0 mL of combined stock reference solution to 20.0 mL with methanol.
3. Urine calibrators. Into separate 10-mL volumetric flasks, pipette 300 μL, 100 μL, 50 μL, and 25 μL of combined intermediate reference solution (100 μg/mL) and dilute the volume with drug-free urine. This provides urine calibrators that contain 3000, 1000, 500, and 250 ng/mL each of amphetamine and methamphetamine. For routine use, one (500 ng/mL) or two (100 ng/mL; 500 ng/mL) calibrators is acceptable.
4. Internal standard solution (amphetamine-D_5 and methamphetamine-D_5, 25 μg/mL each). Dilute 1.0 mL of amphetamine-D_5 and 1.0 mL of methamphetamine-D_5 (100 μg/mL each; Cerilliant, Round Rock, TX.) to 4.0 mL with methanol (chromatographic grade).
5. Sodium periodate, 0.35 mol/L. Dissolve 7.5 g of sodium periodate in 100 mL of deionized water.
6. Carbonate-bicarbonate buffer, pH 9. Dissolve 20 g of sodium bicarbonate and 10 g of potassium carbonate in 200 mL of deionized water.
7. Derivatizing reagent. Dilute 4-carbethoxyhexafluorobutyryl chloride (also named ethyl hexafluoroglutaryl chloride, Lancaster Synthesis, Inc.) 1:100 (vol/vol) with methylene chloride. Prepare fresh weekly.

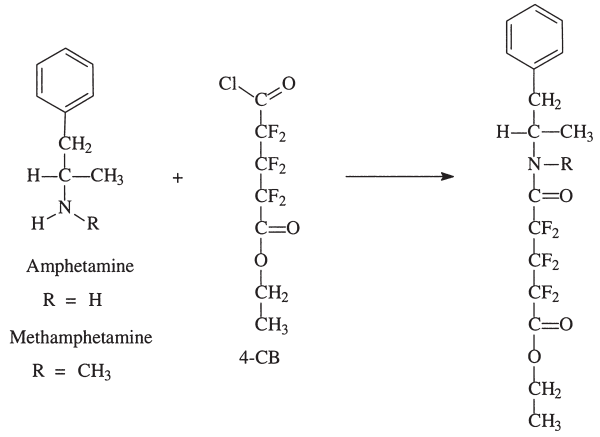

Figure A34-8 Amphetamine derivatization. (4-CB)

Procedure

1. Transfer 4.0 mL of unknown, calibrator, or control to a screw-cap 16 × 125-m test tube and add 100 μL of internal standard and mix.
2. Add 1.0 mL of carbonate-bicarbonate buffer, pH 9, and mix.
3. Add 1.0 mL of sodium periodate (0.35 mol/L), mix, and let stand at room temperature for 10 minutes.
4. Transfer most of the contents to a Toxi-Tube A extraction tube (Varian, Lake Forest, Calif.) and mix by inversion for 30 seconds.
5. Centrifuge for 5 minutes at 1000 ×*g* and transfer the upper organic phase to a 5-mL disposable centrifuge tube.
6. Add 200 μL of derivatizing reagent and 2 drops of triethylamine (Sigma-Aldrich Chemical Co., St. Louis, MO). Mix in a vortex mixer and let stand at room temperature for 10 minutes; add 400 μL of ethanol,* mix, and let stand for an additional 5 minutes.
7. Evaporate to dryness under a stream of air at 37 °C.
8. Reconstitute with 200 μL of ethyl acetate, mix in a vortex mixer, centrifuge for 1 minute (1000 ×*g*), transfer the supernatant to an autosampler vial, and inject 1 μL into the GC-MS.

Interpretation

Characteristic ions monitored are 248, 266, and 294 (amphetamine); 251, 270, and 298 (amphetamine-D_5); 118, 262, 280, and 308 (methamphetamine); and 266, 284, and 312 (methamphetamine-D_5). Positive identification requires qualifier ion ratios at appropriate retention time to be within 20% of those for the calibrators. Qualifier ion ratios are 248:294, 266:294 (amphetamine); 270:298 (amphetamine-D_5); 118:308, 262:308, and 280:308 (methamphetamine); and 284:312 (methamphetamine-D_5). Approximate retention times are 6.3 minutes for amphetamine and 6.4 minutes for methamphetamine. For quantitation the ion ratios 294:298 (amphetamine) and 308:312 (methamphetamine) are compared with those for the calibrators. Based on the Substance Abuse and Mental Health Services Administration (SAMHSA) guidelines,

*Substitution of other alcohols (e.g., methanol or propanol) will result in transesterification of the ethyl ester portion of the 4-carbethoxyhexafluorobutyryl chloride (4-CB) derivatives and produce two components in the chromatogram (e.g., 4-carbethoxy and 4-carbmethoxy derivatives).

METHOD 34-14 Determination of Amphetamine and Methamphetamine (and MDA, MDMA, MDEA) in Urine by Gas Chromatography-Mass Spectrometric Analysis—cont'd

samples with amphetamine or methamphetamine concentrations >500 ng/mL are judged as positive results.

Comments

Specimens that contain ephedrine or pseudoephedrine have been reported to have positive test results for methamphetamine when using the 4-carbethoxyhexafluorobutyryl chloride (4-CB) derivatizing reagent. This phenomenon appears to result from a reaction that occurs within a newly silanized injection liner in which the hydroxyl group of pseudoephedrine and, to a lesser extent, of ephedrine is replaced by hydrogen to form methamphetamine-4-CB. To guard against a false-positive report of methamphetamine owing to the presence of ephedrine or pseudoephedrine, SAMHSA regulations require identification of methamphetamine (cutoff, 500 ng/mL) and of its metabolite, amphetamine (cutoff, 200 ng/mL). Amphetamine-4-CB is not formed from α-hydroxyamines. However, the requirement for amphetamine ≥200 ng/mL may not be satisfied in some cases of known methamphetamine ingestion, especially during the initial 12-hour postdose period, leading to false negative results. To increase the detection rate for amphetamine and methamphetamine, SAMHSA has proposed a reduction of the screening and confirmation cutoff from 1000 ng/mL and 500 ng/mL to 500 ng/mL and 250 ng/mL, respectively. Methamphetamine would require the presence of at least 100 ng/mL of an amphetamine metabolite for a positive result. In a 2002 study by Oyler and colleagues (Clin Chem 2002;48:1703-14), these lower cutoff values increased the detection rate for methamphetamine by 48% compared with current cutoff values. Moreover, the highest detection rate for methamphetamine was achieved by use of the 250-ng/mL cutoff with elimination of the amphetamine requirement. In the described procedure, periodate oxidation before derivatization destroys α-hydroxyamines and therefore eliminates the possible false report of methamphetamine owing to their presence. Under the stated conditions, no methamphetamine or residual α-hydroxyamine was detected when pseudoephedrine or ephedrine was initially present in the urine specimen at a concentration of 1 mg/mL, effectively negating the amphetamine requirement.

Propylhexedrine and phentermine are nonhydroxy sympathomimetic amines not oxidized by sodium periodate. Their 4-CB derivatives have retention times distinguishable from those of methamphetamine-4-CB (0.95 and 0.79 relative to methamphetamine). Moreover, neither propylhexedrine nor phentermine 4-CB derivatives fragment to the 118 ion characteristic of methamphetamine-4-CB. This ion may optionally be included for added assurance of methamphetamine identification.

Adaptation to include MDA, MDMA, and MDEA

MDA, MDMA, and MDEA may be included in the GC-MS analysis for amphetamine and methamphetamine albeit with higher detection limits (Figure A34-9). MDA, MDMA, and MDEA may be purchased from Sigma-Aldrich; MDA-D_5, MDMA-D_5, and MDEA-D_6 are available from Cerilliant, Round Rock, TX. Selected ions for monitoring are 248, 266, and 294 (MDA); 251, 270, and 298 (MDA-D_5); 262, 280, and 308 (MDMA); 266, 284, and 312 (MDMA-D_5); 276, 294, and 322 (MDEA); and 300 and 328 (MDEA-D_6). MDEA-D_6 resulted in a lower baseline response than MDEA-D_5. With the procedure described, the lower limit of detection of these designer amphetamines is approximately 200 ng/mL compared with 100 ng/mL for amphetamine and methamphetamine. If necessary an improved limit of detection may be achieved by the addition of 100 µL of ethyl acetate instead of 200 µL at step 8. Alternatively, 8 mL of urine instead of 4 mL may be extracted.

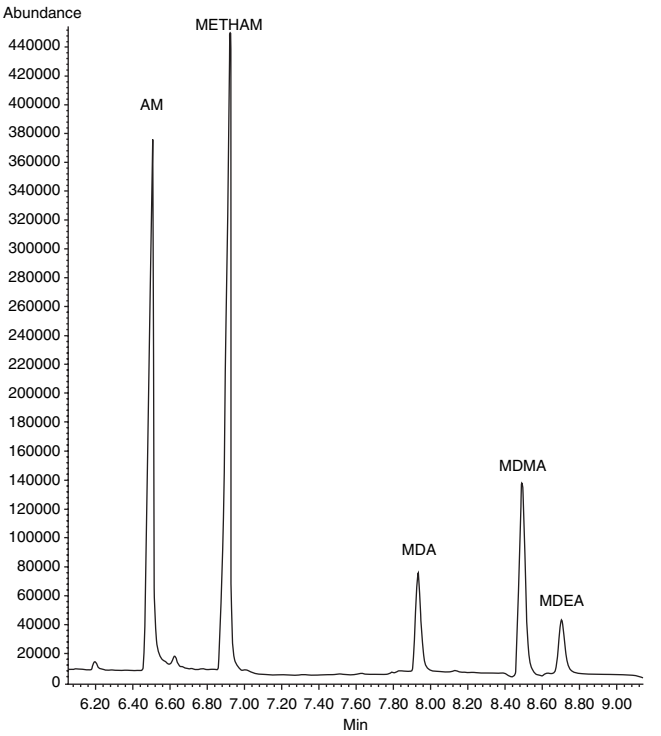

Figure A34-9 Total-ion chromatogram for amphetamine and/or amphetamine-like drugs. Amphetamine (AM); methamphetamine (Metham); methylenedioxyamphetamine (MDA); methylenedioxymethamphetamine (MDMA); methylenedioxyethylamphetamine (MDEA).

METHOD 34-15 Determination of Barbiturates by Capillary Gas Chromatographic Analysis

Principle

After the addition of internal standard (aprobarbital), barbiturates in serum are extracted twice with diethyl ether, and the ether is dehydrated with solid sodium sulfate and then evaporated to dryness. The residue is dissolved in 50 µL of ethyl acetate, and an aliquot is injected into the gas chromatograph.

Instrumentation

For analysis a gas chromatograph equipped with a capillary column (15 m × 0.25 mm ID, DB-5; J & W Scientific, Folsom, CA.), a flame ionization detector, temperature programming, and split sample injection (split ratio 1:20) are used. Helium carrier gas flow is 30 cm/sec. Conditions of operation are injector, 250 °C; detector, 300 °C; initial oven temperature, 115 °C (0.75 minutes); and 18 °C/min to 290 °C (2 minutes).

Reagents

1. Combined stock reference solution (1 mg/mL). Transfer 20 mg each (correct for salt) of amobarbital, butalbital, pentobarbital, phenobarbital, and secobarbital to a 20-mL volumetric flask, dissolve in and dilute to volume with methanol. Store at −20 °C. The solution is stable for at least 1 year.
2. Working combined calibrator (10 µg/mL of each drug). Transfer 2.0 mL of the combined stock reference solution (1 mg/mL) to a 200-mL volumetric flask and dilute to volume with a solution of bovine serum albumin (60 g/L). Aliquot into 1.2-mL portions and freeze at −20 °C. The calibrator is stable for at least 6 months.
3. Phosphate buffer, 0.15 mol/L, pH 6.4. Combine 80 mL of 0.15 mol/L, KH_2PO_4 (9.08 g/L) with 30 mL of 0.15 mol/L Na_2HPO_4 (9.47 g/L). The pH should be 6.4 ± 0.1. Adjust, if necessary, using the appropriate phosphate solution.
4. Bovine serum albumin (60 g/L). Dissolve 12 g of bovine serum albumin in 200 mL of deionized water.
5. Internal standard (200 µg/mL). Transfer 10 mg of aprobarbital to a 50-mL volumetric flask, dissolve in and dilute to volume with methanol. The solution is stable at −20 °C for 1 year.

Procedure

1. Pipette 1.0 mL of calibrator, control, or the patient's sera into separate 15-mL glass-stoppered test tubes.
2. Add 1.0 mL of phosphate buffer and mix.
3. Add 100 µL of internal standard and mix.
4. Add 5 mL of diethyl ether, cap the test tubes, and shake gently to mix. Allow the layers to separate and remove the upper ether layer.
5. Repeat the extraction with an additional 5 mL of ether.
6. Combine the ether extracts, add about 1 g of anhydrous sodium sulfate, mix in a vortex mixer for 5 to 10 seconds, and decant the ether.
7. Evaporate the ether at 40 °C to 50 °C under a stream of air.
8. Dissolve the residue in 50 µL of ethyl acetate and inject 0.5 µL into the gas chromatograph.

Interpretation

Identification of barbiturates present in a patient's specimen is based on coincidence of the retention time (±0.05 minutes) for any peaks present to those for the calibrators (Figure A34-10). For quantitation the peak height ratio of the drug to the internal standard is compared with the similar ratio for the respective calibrator.

$$\text{Concentration, } \frac{\text{mg}}{\text{mL}} = \frac{R_u}{R_c} \times C_c$$

where

R_u = peak height ratio for the unknown

R_c = peak height ratio for the calibrator

C_c = concentration of the calibrator (µg/mL)

METHOD 34-16 Determination of Barbiturates in Urine by Gas Chromatography-Mass Spectrometry

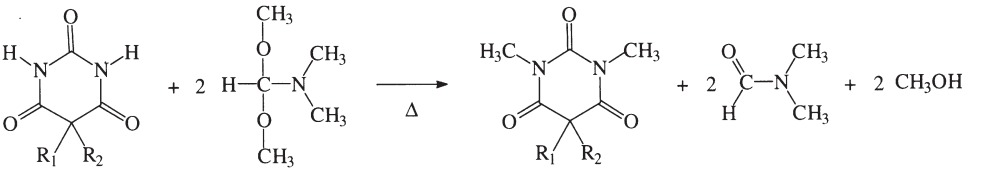

Figure A34-11 Methylation of barbiturates.

Principle

A urine specimen that has tested positive for barbiturates by immunoassay is extracted (liquid-liquid); the extract is dried and then treated with N,N-dimethylformamide dimethyl acetal to form methyl derivatives of the barbiturates (Figure A34-11). Following the addition of a buffer, the methylated barbiturates are extracted with hexane and analyzed by GC-MS. Pentobarbital-D_5 and phenobarbital-D_5 are used as internal standards for quantitation.

Instrumentation

A GC-MS equipped with a capillary column (e.g., 25 m × 0.2 mm ID, 0.33-µm film thickness; J & W Scientific Ultra-2) is required for analysis. The operating conditions with this column for splitless sample injection are injection port, 250 °C; detector, 315 °C; initial temperature, 100 °C (0.5 minutes); temperature program, 30 °C/min to 235 °C (2 minutes); carrier gas, He; and pressure programmed to maintain a constant flow of 0.9 mL/min.

Reagents

1. Combined stock reference solution (1 mg/mL of each barbiturate). Quantitatively transfer 0.0110 g each of pentobarbital sodium salt and secobarbital sodium salt, and 0.0100 g each of phenobarbital, butalbital, butabarbital, and amobarbital (all from Sigma-Aldrich Chemical Company, St. Louis) to a 10-mL volumetric flask. Dissolve in and dilute to the mark with methanol. Store refrigerated in a brown bottle.
2. Combined intermediate reference solution 1 (100 µg/mL of each barbiturate). Dilute 1.0 mL of barbiturate stock reference solution to 10.0 mL with deionized water. Store refrigerated in a brown bottle.
3. Combined intermediate reference solution 2 (10 µg/mL of each barbiturate). Dilute 1.0 mL of barbiturate stock reference solution to 100 mL with deionized water. Store refrigerated in a brown bottle.
4. Barbiturate calibrators in urine. Combine appropriate volumes of intermediate reference solution 1 (100 µg/mL) or 2 (10 µg/mL) with corresponding appropriate volumes of drug-free urine to provide calibrators with 100, 500, 1000, and 2000 ng/mL each of barbiturate. For routine calibration, the use of one (500 ng/mL) or two (100 and 500 ng/mL) calibrators is acceptable.
5. Internal standard. Dilute 1.0 mL each of pentobarbital-D_5 and phenobarbital-D_5 (100 µg/mL each; Cerilliant, Round Rock, TX.) to 4.0 mL with methanol.
6. Sodium acetate buffer, pH 7.3. Dissolve 50 g of sodium acetate trihydrate in 500 mL of deionized water and adjust pH to 7.1 to 7.5 with HCl (0.2 mol/L).
7. Extraction solvent. Toxi-Tube B (Varian, Lake Forest, Calif.).

Procedure

1. Add 4.0 mL of calibrator, control, or the patient's urine specimen to separate labeled extraction tubes (Toxi-Tube B). Add 100 µL of internal standard and mix by inversion for 1 minute.

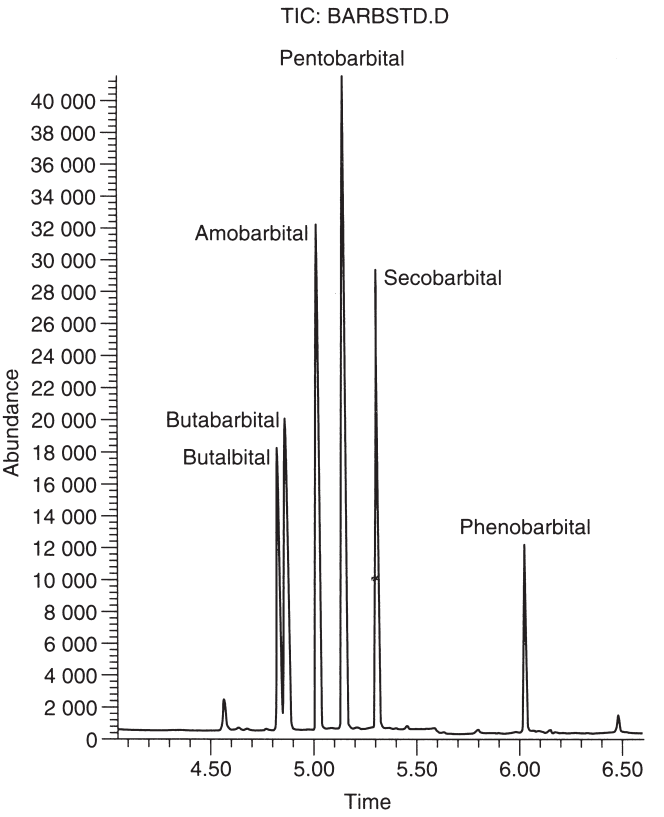

Figure A34-12 Total-ion chromatogram for methylated barbiturates. Time = minutes.

2. Centrifuge (1000 ×*g*) for 5 minutes and transfer the organic layer to labeled 5-mL disposable centrifuge tubes. Evaporate to dryness at 37 °C under a stream of air.
3. Add 100 µL of dimethylformamide (Fisher Scientific, Pittsburgh) and 100 µL of N,N-dimethylformamide dimethyl acetal (Sigma-Aldrich Chemical Co., St. Louis). Heat at 130 °C for 2 to 5 minutes.
4. Cool the tubes under cold tap water for 15 seconds. Add 1 mL of acetate buffer and 1 mL of hexane; cap and vortex mix.
5. Transfer upper hexane layer to the autosampler vial and inject 1 µL into the GC-MS.

Interpretation

The methyl derivatives of the analyzed barbiturates are adequately resolved under the chromatographic conditions described (Figure A34-12). Approximate retention times and characteristic ions selected for monitoring are given in Table A34-1. Note that butalbital, butabarbital, and secobarbital have similar mass spectra, as is true for amobarbital and pentobarbital. Thus distinction between each member of the group of barbiturates with shared selected ions

METHOD 34-17 Determination of Benzodiazepines in Urine by Gas Chromatography-Mass Spectrometry

Principle

Urine specimens that have tested positive for benzodiazepines by immunoassay are treated with β-glucuronidase, subjected to liquid-liquid extraction, and the extracts evaporated. The residue is treated with N-methyl-N-trimethylsilyl-trifluoroacetamide (MSTFA) to form trimethylsilyl (TMS) derivatives of the benzodiazepines, which are analyzed by selected ion-monitoring GC-MS; deuterated internal standards are used for quantification.

Instrumentation

A GC-MS equipped with a capillary column (e.g., 25 m × 0.2 mm ID, 0.33-μm film thickness; J & W Scientific Ultra 2) is required for analysis. The operating conditions with this column for splitless injection are injection port, 250 °C; detector, 315 °C; initial temperature, 70 °C (1 minute); temperature program, 30 °C/min to 320 °C (hold for 4 minutes); carrier gas, He; and pressure programmed to maintain a constant flow of 0.9 mL/min.

Reagents

1. Combined stock reference solution (1.0 mg/mL of each benzodiazepine). Weigh and quantitatively transfer 0.0100 g of oxazepam, nordiazepam, lorazepam, temazepam, N1-(2-hydroxyethyl)flurazepam, α-hydroxyalprazolam, α-hydroxytriazolam, and 7-aminoclonazepam into the same 10.0-mL volumetric flask. Dissolve and dilute to volume with methanol.
2. Combined intermediate reference solution (100 μg/mL of each benzodiazepine). Dilute 1.0 mL of combined stock reference solution (1 mg/mL) to 100 mL with deionized water.
3. Benzodiazepine calibrators in urine.

3.1 Calibrator 1, 100 ng/mL. Dilute 100 μL of combined intermediate reference solution and 10 μL of α-hydroxymidazolam reference solution (100 μg/mL of methanol; Cerilliant, Round Rock, TX.) to 10.0 mL with benzodiazepine-free urine. Prepare fresh.

3.2 Calibrator 2, 500 ng/mL. Dilute 500 μL of combined intermediate reference solution and 50 μL of α-hydroxymidazolam reference solution (100 μg/mL of methanol) to 10.0 mL with blank urine. Prepare fresh.

4. Combined working internal standard reference solution. Transfer 1.0 mL each of α-hydroxyalprazolam-D_5, α-hydroxytriazolam-D_4, lorazepam-D_4, nordiazepam-D_5, temazepam-D_5 and 2-hydroxy-ethylflurazepam-D_4 (all 100 μg/mL; Cerilliant, Round Rock, TX.), and 0.2 mL of oxazepam-D_5 (1.0 mg/mL) to the same 10.0-mL volumetric flask; dilute to the mark with methanol.
5. β-Glucuronidase: *Patella vulgata;* type L-11 (Sigma-Aldrich Chemical Co., St. Louis, MO). Reconstitute with 5 mL of deionized water. The solution is stable for 30 days at 4 °C.
6. MSTFA (Pierce Chemical Co., Rockford, IL.).
7. Extraction solvent. Toxi-Tube A (Varian, Lake Forest, CA.).
8. Sodium acetate buffer, 0.55 mol/L, pH 5. Dissolve 7.41 g of sodium acetate in deionized water, add 1.1 mL of glacial acetic acid, mix, and dilute to 100 mL with deionized water.

Procedure

1. To labeled 16 × 125-mm screw-capped test tubes, add 5.0 mL of urine (unknown, calibrator, or control), 100 μL of a combined working internal standard, 100 μL of β-glucuronidase, and 0.5 mL of sodium acetate buffer (0.55 mol/L, pH 5). Cap, mix, and incubate at 60 °C for 1 hour.

Continued.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 34-17 Determination of Benzodiazepines in Urine by Gas Chromatography-Mass Spectrometry

2. Allow tubes to cool and transfer contents to a Toxi-Tube A; mix by inversion for 30 seconds.
3. Centrifuge at 1000 × *g* for 2 minutes; transfer organic layer to a 13 × 100-mm test tube. Evaporate to dryness at 60 °C under a gentle stream of air.
4. Add 100 µL of MSTFA and vortex mix; add 100 µL of hexane, mix, transfer to an autosampler vial, and inject 1 µL.

Interpretation

The TMS derivatives of the analyzed benzodiazepines are adequately resolved under the chromatographic conditions described (Figure A34-13). Approximate retention times and characteristic ions selected for monitoring are listed in Table A34-2. Identification of each benzodiazepine is based on the characteristic ion ratios and retention times as described for other drugs determined by selected ion monitoring.

METHOD 34-18 Determination of Δ^9-THC-COOH in Urine by Gas Chromatography-Mass Spectrometry

Principle

Following addition of internal standard (d_6-Δ^9-THC-COOH), urine is treated with alkali to hydrolyze the glucuronide of Δ^9-THC-COOH. The Δ^9-THC-COOH and internal standard are extracted into an organic solvent and, after removal of solvent by evaporation, are converted to TMS derivatives (see Figure A34-14). The reaction mixture is analyzed by GC-MS using selected ion monitoring at mass units of 371, 473, and 488 (Δ^9-THC-CO_2-TMS_2) and 377, 476, and 494 (d_6-Δ^9-THC-CO_2-TMS_2).

The characteristic ratio of the integrated ion currents 488:371 and 473:371 at the appropriate retention time provides verification of the presence of Δ^9-THC-COOH. Comparison of the ratio 371:377 with appropriate reference materials allows for its quantitation.

Specimen

A 10-mL aliquot of randomly collected urine is required for analysis. To prevent specimen foaming, avoid excessively vigorous mixing.

Instrumentation

A GC-MS equipped with a fused silica capillary column (e.g., 25 m × 0.2 mm ID, 0.33-µm film thickness; J & W Scientific Ultra 2) is required for analysis. The operating conditions with this column for splitless sample injection are injection port, 200 °C; detector, 315 °C; initial temperature, 70 °C (0.5 minutes); temperature program, 30 °C/min to 300 °C (hold, 3 minutes).

Reagents

1. Δ^9-THC-COOH calibrators in urine. Drug-free urine is first made alkaline (0.1 mol/L KOH) to prevent absorption of Δ^9-THC-COOH onto glass surfaces. This may be accomplished by adding an appropriate amount of 8 mol/L of potassium hydroxide (used below) to drug-free urine. Allow to stand for 10 minutes and then centrifuge at 1000 × *g* for 10 minutes. Add appropriate amounts of the Δ^9-THC-COOH stock reference solution (100 µg/mL; Cerilliant, Round Rock, TX.) to appropriate volumes of this alkalinized, drug-free urine to provide Δ^9-THC-COOH concentrations of 10, 50, 100, 200, and 400 ng/mL. Aliquots are stable for at least 3 months at −10 °C to −20 °C. For routine use, one (50 ng/mL) or two (10 and 50 ng/mL) calibrators is adequate.
2. d_6-Δ^9-THC-COOH stock internal standard, 100 µg/mL (Elsohly Laboratories, Inc., Oxford, MI.).
3. d_6-Δ^9-THC-COOH working internal standard, 2 µg/mL. Dilute 0.5 mL of stock d_6-Δ^9-THC-COOH internal standard (100 µg/mL) to 25.0 mL with methanol. Store at −10 °C to −20 °C.
4. Potassium hydroxide, 3 mol/L. Dissolve 33.7 g of potassium hydroxide in 200 mL of deionized water.
5. Potassium hydroxide, 8 mol/L. Dissolve 45 g of potassium hydroxide in 100 mL of deionized water.
6. Phosphate buffer, pH 1.8. Place 375 mL of deionized water in an Erlenmeyer flask. Slowly add 33.7 mL of 85% phosphoric acid. Add potassium hydroxide (8 mol/L) until a pH of 1.7 is achieved. Adjust volume to 500 mL with deionized water. Adjust final pH to 1.8 if necessary.
7. Extraction solvent 7:1 (vol/vol) hexane:ethyl acetate. Combine 350 mL of hexane with 50 mL of ethyl acetate.
8. Derivatizing reagent. MSTFA (Pierce Chemical Co., Rockford, IL., No. 48910).

Procedure

1. Properly label 16 × 125-mm screw-capped tubes.
2. Add 1.0 mL of 3 mol/L potassium hydroxide to control and the patient's tubes only.
3. Transfer 5.0 mL of calibrator, control, or the patient/subject's urine to the appropriate tube.
4. Add 100 µL of working internal standard. Cap (Teflon-lined) and invert to mix.
5. Incubate all tubes at 37 °C for 15 minutes.
6. Add 3 mL of pH 1.8 phosphate buffer to each tube.
7. Add 5 mL of extraction solvent (hexane:ethyl acetate, 7:1 [vol/vol]).
8. Gently mix for 5 minutes. (Do not shake.)
9. Centrifuge all tubes at 1000 ×*g* for 10 minutes.
10. Transfer organic phase to 13 × 100-mm culture tubes.
11. Evaporate just to dryness at 37 °C under air flow.
12. Add 50 µL of MSTFA and 50 µL ethyl acetate, mix.
13. Transfer to an autosampler vial and inject 1 µL.

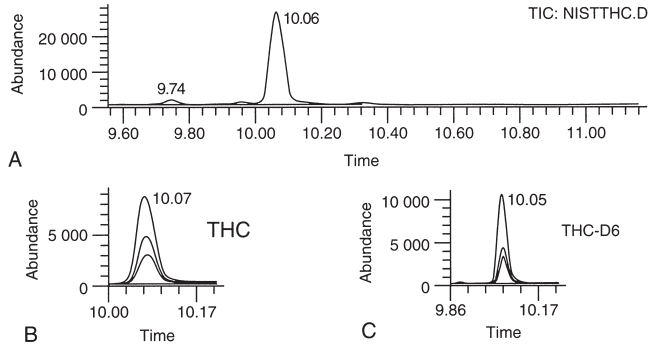

Figure A34-14 A, Total-ion chromatogram for THC-COO-TMS_2, 15ng/mL. **B,** integrated ion currents for THC-COO-TMS_2, in descending order of abundance: 371, 473, and 488 amu. **C,** integrated ion currents for D_6-THC-COO-TMS_2, in descending order of abundance: 377, 476, and 494 amu. Time = minutes.

Interpretation

Characteristic ions in the mass spectrum of Δ^9-THC-CO_2-TMS_2 are 371, 473, and 488 and for d_6-Δ^9-THC-CO_2-TMS_2, 377, 476, and 494. Positive identification of Δ^9-THC-COOH in an unknown requires that the integrated ion current ratios, 488:371 and 473:371, at the appropriate retention time, should be ±20% of the corresponding ratios for the calibrators (see Figure 34-44 in the text). Moreover, internal standard qualifier ion ratios, 476:377 and 494:377, for the unknown should correspond (±20%) with those for the reference materials.

For quantitation a calibration curve is prepared by plotting the ion ratio 371:377 against the calibrator concentration of Δ^9-THC-COOH. The concentration of the unknown is then computed from this plot. Based on guidelines established by SAMHSA, specimens that contain more than 15 ng/mL of Δ^9-THC-COOH are considered positive evidence for marijuana use (see Table 34-9 in the text).

METHOD 34-19 Determination of Benzoylecgonine in Urine by Gas Chromatography-Mass Spectrometry

Principle

An internal standard (benzoylecgonine-D_3) is added to urine specimens that have tested positive for benzoylecgonine by immunoassay. Following liquid-liquid extraction and solvent evaporation, the residue is treated with MSTFA to form benzoylecgonine (and ecgonine methyl ester) TMS derivatives. The reaction mixture is analyzed by GC-MS using selected ion monitoring at mass units of 82, 240, and 361 (benzoylecgonine-TMS), and 85, 243, and 364 (benzoylecgonine-D_3-TMS). Additional ions may be monitored, if desired, to include determination of cocaine (82, 182, and 303); ecgonine methyl ester-TMS (82, 96, and 271); cocaethylene (82, 196, and 317); and ecgonine ethyl ester-TMS (82, 96, and 285).

Instrumentation

A GC-MS equipped with a data station and a fused silica capillary column (e.g., 25 m × 0.2 mm ID, 0.33-μm film thickness; J & W Scientific Ultra 2) are required for analysis. The operating conditions with this column for splitless sample injection are injection port, 200 °C; detector, 315 °C; initial temperature, 125 °C (0.5 minutes); temperature program, 35 °C/min to 280 °C (2 minutes).

Reagents

1. Benzoylecgonine stock reference solution, 100 μg/mL. Transfer 0.0125 g of benzoylecgonine tetrahydrate (Alltech-Applied Science Lab, State College, PA.) to a 100-mL volumetric flask. Dissolve in and dilute to the mark with methanol. Store at −10 °C to −20 °C.
2. Benzoylecgonine intermediate stock reference solution, 10 μg/mL. Dilute 1.0 mL of stock reference solution (100 μg/mL) to 10.0 mL with methanol. Store at −10 °C to −20 °C.
3. Benzoylecgonine calibrators in urine. Dilute appropriate volumes of either stock reference solution or intermediate reference solution with drug-free urine to provide final concentrations of benzoylecgonine of 100, 500, 1000, and 5000 ng/mL. Prepare fresh. For routine use, one (500 ng/mL) or two (100 and 500 ng/mL) calibrators is adequate.
4. Internal standard benzoylecgonine-D_3, 25 μg/mL. Dilute 1.0 mL of stock benzoylecgonine-D_3 (100 μg/mL; Cerilliant, Round Rock, TX.) to 4.0 mL with methanol (HPLC grade).
5. Buffer, pH 9. Dissolve 20 g of sodium bicarbonate ($NaHCO_3$) and 10 g of potassium carbonate (K_2CO_3) in 200 mL of deionized water.
6. Extraction solvent, dichloromethane:isopropanol (9:1 vol/vol). Combine 450 mL of dichloromethane with 50 mL of isopropanol.
7. MSTFA (Pierce Chemical Co., Rockford, IL., No. 48910).

Procedure

1. To 2.0 mL of unknown, calibrator, or control urine in a screw-cap 16 × 125-mm test tube, add 100 μL of internal standard and mix.
2. Add 2.0 mL of pH 9 buffer and mix.
3. Add 8 mL of extraction solvent and shake test tubes for 5 minutes.
4. Centrifuge for 5 minutes at 1000 ×*g* and then discard the aqueous (upper) layer.
5. Transfer the organic phase to a 5-mL disposable centrifuge tube (Kimble No. 73790) and evaporate to dryness at 40 °C under a stream of air.
6. Add 100 μL of MSTFA reagent, cap, and heat at 60 °C for 15 minutes. Allow the tube to cool, transfer to an autosampler vial, and inject 1 μL into the GC-MS.

Interpretation

Identification of benzoylecgonine is based on its characteristic qualifier ion ratios normalized to the corresponding ion ratios for the deuterated internal standard. Thus the ion ratios 361:240 and 82:240 divided by the corresponding deuterated ions (364:243 and 85:243) should be 1.0 ± 0.2. In addition, the retention time for the deuterated and nondeuterated ions should not vary by more than 2%. The use of normalized ion ratios compensates for any changes in the mass spectrometer ion source at the time of analysis.

The concentration of benzoylecgonine in the unknown is determined from the calibration curve prepared by comparing the ion ratio 240:243 with the concentration of benzoylecgonine in the calibrator. For routine calibration, a single calibrator is also acceptable. Based on criteria established by SAMSHA, benzoylecgonine concentrations greater than 150 ng/mL are considered positive evidence of the use of cocaine; the Department of Defense has established the cutoff value at 100 ng/mL. However, SAMHSA has proposed a reduction of the screening and confirmation cutoff values to 150 ng/mL and 100 ng/mL, respectively.

METHOD 34-19 Determination of Benzoylecgonine in Urine by Gas Chromatography-Mass Spectrometry—cont'd

Cocaine, ecgonine methyl ester, cocaethylene, and ecgonine ethyl ester may also be analyzed (Figure A34-15). Their presence may be verified by a comparison of their characteristic qualifier ion ratios, at the appropriate retention time, with those of the calibrators. These ratios should not differ by more than 20%. Inclusion of appropriate deuterated internal standards would allow for calculation of normalized qualifier ion ratios and for their quantitation.

METHOD 34-20 Determination of γ-Hydroxybutyrate by Gas Chromatography-Mass Spectrometry

Principle

A urine specimen is treated with acidified acetonitrile and then dehydrated by evaporation. Gamma hydroxybutyrate (GHB) is converted to its bis(trimethylsilyl) derivative by MSTFA and analyzed by GC-MS in ion-selected mode using GHB-D_6 as the internal standard.

Instrument

A GC-MS equipped with a fused silica capillary column (e.g., 25 m × 0.2 mm ID, 0.33-μm film thickness of cross-linked 5% phenylmethyl silicon, J & W Scientific) operated at an initial oven temperature of 60 °C for 0.75 minutes and then increased 20 °C/min to a final temperature of 180 °C.

Reagents

1. GHB stock standard, 1000 mg/dL. Transfer 0.612 g of GHB, sodium salt (Sigma-Aldrich, St. Louis) to a 50-mL volumetric flask. Dissolve in and dilute to the mark with reagent-grade water. This solution is stable for 1 year at −10 °C to −20 °C.
2. GHB calibrator, 1 mg/dL. Transfer 50 μL of stock standard to a 50-mL volumetric flask, dilute to volume with pooled GHB-free urine. Transfer 300 μL of aliquots to 12 × 75-mm polystyrene test tubes, cap, and store at −10 °C to −20 °C. This solution is stable for 6 months.
3. GHB calibrator, 10 mg/dL. Transfer 0.5 mL of stock standard to a 50-mL volumetric flask and dilute to volume with GHB-free urine. Transfer 300 μL of aliquots to 12 × 75-mm polystyrene test tubes, cap, and store at 10 °C to −20 °C. This solution is stable for 6 months.
4. Internal standard, GHB-D_6, 17 μg/mL. Transfer the contents of one vial GHB-D_6 (Cerilliant, Round Rock, TX.) to a 10-mL brown glass bottle. Add 5 mL of acetonitrile acetic acid (88/12, vol/vol). Mix and store at 2 °C to 8 °C. This solution is stable for 6 months.

Procedure

1. To separately labeled 5-mL disposable snap-cap centrifuge tubes, transfer 50 μL of each calibrator, control, pooled urine blank, and the patient's specimen (neat and diluted 1:100 with reagent-grade water).
2. Add 100 μL of internal standard solution and vortex mix.
3. Add 600 μL of acetonitrile and vortex.
4. Place the tubes in an 80 °C heat block and dry under stream of air. Add 25 μL of N,N,-dimethylformamide and vortex; add 150 μL of MTSFA (Pierce Chemical Co.) and 150 μL of ethyl acetate and vortex again.
5. Transfer 200 μL of aliquots to autosampler vials and inject 1 μL.

Continued.

METHOD 34-20 Determination of γ-Hydroxybutyrate by Gas Chromatography-Mass Spectrometry—cont'd

Interpretation

Characteristic ions monitored are 233, 234, and 235 for GHB and 239, 240, and 241 for GHB-D_6. Positive identification requires qualifier ion ratios at appropriate retention time to be within 20% of those of the calibrators. For quantitation, the ion ratio 233/239 for the unknown is compared with those of the calibrators. The approximate retention time is 6 minutes. The method is linear to 10.0 mg/dL, but is effectively extended to 1000 mg/dL by optional autoinclusion of a diluted (1:100) specimen. To ensure discrimination between endogenous and exogenous GHB, a cutoff of 1.0 mg/dL is appropriate.

METHOD 34-21 Determination of Opiates in Urine by Gas Chromatography-Mass Spectrometry

Principle

Urine specimens that have tested positive for opiates by immunoassay are hydrolyzed by β-glucuronidase in the presence of hydroxylamine to convert conjugates to free drugs and to transform keto-opiates (hydrocodone, hydromorphone, oxycodone, and oxymorphone) to their respective oximes. Following solid phase extraction, the organic eluate is evaporated, and then reconstituted with MSTFA to form TMS derivatives, which are analyzed by selected ion-monitoring GC-MS using deuterated internal standards (Figure A34-16).

Note: This procedure is optimized for a confirmatory cutoff concentration of 300 ng/mL. A modification in calibrator concentrations and volume of urine will be required for a cutoff value of 2000 ng/mL.

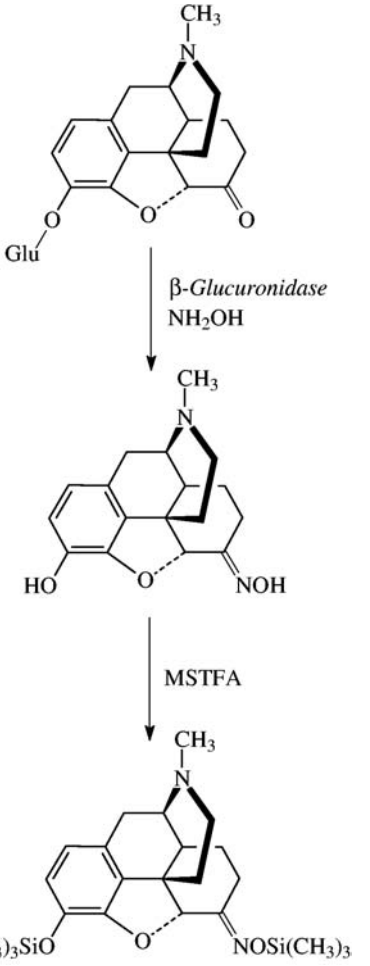

Figure A34-16 Hydrolysis and derivatization of opiates; hydromorphone example.

Instrumentation

A GC-MS equipped with a capillary column (e.g., 25 mm × 0.2 mm ID, 0.33-μm film thickness; J & W Scientific Ultra 2) is required for analysis. The operating conditions with this column for splitless injection are injection port, 250 °C; detector, 315 °C; initial temperature, 70 °C (1.0 minute); temperature program, 30 °C/min to 240 °C, then 15 °C/min to 280 °C.

Reagents

1. Combined stock reference solution (1 mg/mL of each opiate). Transfer 10 mg of codeine, 15 mg of dihydrocodeine bitartrate, 10.6 mg of morphine monohydrate (all from Alltech-Applied Science Labs, State College, PA.), 15 mg of hydrocodeine bitartrate, 11.3 mg of hydromorphone, 10.3 mg of norcodeine, and 11.1 mg of oxycodone HCl (all from Sigma-Aldrich, St. Louis) to a 10.0-mL volumetric flask. Dissolve in and dilute to volume with methanol:deionized water (50:50, vol/vol).
2. Combined intermediate reference solution (10 μg/mL of each opiate). Dilute 1.0 mL of combined stock reference solution plus 1.0 mL of oxymorphone (1 mg/mL in methanol; Cerilliant, Round Rock, TX.) to 100.0 mL with deionized water.
3. Calibrators. Combine appropriate volumes of an intermediate reference solution with opiate-free urine to provide opiate concentrations of 100 ng/mL, 500 ng/mL, 1000 ng/mL, and 2000 ng/mL. For routine use, one (500 ng/mL) or two (100 ng/mL and 500 ng/mL) calibrators is adequate.
4. Combined internal standards (10 μg/mL each of opiate). Transfer 1.0 mL each of codeine-D_3, hydrocodone-D_3, oxycodone-D_6, hydromorphone-D_3, morphine-D_3, and oxymorphone-D_3 (all 100 μg/mL in methanol; Cerilliant, Round Rock, TX.) to a 10.0-mL volumetric flask and dilute to volume with methanol. β-Glucuronidase. Reconstitute β-glucuronidase (5 million U, limpet; Sigma-Aldrich, St. Louis) with 5.0 mL of deionized water. This solution is stable for 1 month at 2 °C to 8 °C.

Procedure

1. To labeled 16 × 125-mm screw-capped test tubes, add 1.0 mL urine (the patient's and/or subject's, calibrator, or control).

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 34-21 Determination of Opiates in Urine by Gas Chromatography-Mass Spectrometry—cont'd

2. Add 50 µL of internal standard, 100 µL of β-glucuronidase, and 100 µL of hydroxylamine (10 g/dL).
3. Cap and vortex. Incubate at 60 °C for 2 hours.
4. Allow tubes to cool to room temperature and centrifuge 1000 ×*g* for 5 minutes.
5. Transfer the supernatant to the appropriately prepared solid phase extraction column (Cleen Screen ZSDAU020, World-Wide Monitoring Corp., Horsham, PA.) and process according to manufacturer's directions.
6. Evaporate column eluate to dryness.
7. Add 100 µL of MSTFA (Pierce Chemical Co., Rockford, IL.). Transfer to an autosampler vial and inject 1 µL.

Interpretation

The TMS derivatives of the analyzed opiates are adequately resolved under the chromatographic conditions described (Figure A34-17). Approximate retention times and characteristic ions monitored are given in Table A34-3. The keto-opiates—hydrocodone, hydromorphone, oxycodone, and oxymorphone—undergo enolization, which under some analytical conditions may result in a second chromatographic peak for each. Conversion of these keto-opiates to their respective oximes eliminates this keto-enol transformation. The heroin metabolite, 6-acetylmorphine, may also be analyzed as the TMS derivative. 6-Acetylmorphine-TMS elutes after morphine-TMS_2 and is monitored with selected ions 287, 340, and 399.

METHOD 34-22 Determination of Methadone and EDDP in Urine by Gas Chromatography-Mass Spectrometry

Principle

A urine specimen that has tested positive for methadone by immunoassay is extracted (liquid-liquid); the extract is evaporated, reconstituted with ethyl acetate, and analyzed by selected ion-monitoring GC-MS. Methadone-D_3 and 1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP)-D_3 are used as internal standards for quantitation of methadone and EDDP.

Instrumentation

A GC-MS equipped with a capillary column (e.g., 25 m × 0.2 mm ID, 0.33-μm film thickness; J & W Scientific Ultra 2) is required for analysis. The operating conditions with this column for splitless injection are injection port, 200 °C; detector, 315 °C; initial temperature, 70 °C; temperature program, 25 °C/min; final temperature, 280 °C; carrier gas, He; pressure programmed to maintain a constant flow of 0.9 mL/min.

Reagents

1. Stock reference solution (1.0 mg/mL each of methadone and EDDP). Quantitatively, transfer 0.0112 g of methadone HCl (Alltech-Applied Science, State College, Pa.) and 0.0140 g of EDDP perchlorate (Cerilliant; Round Rock, TX.) to a 10.0-mL volumetric flask; dissolve in and dilute to volume with methanol.
2. Intermediate reference solution 1 (100 μg/mL each of methadone and EDDP). Dilute 1.0 mL of a stock reference solution to 10.0 mL with deionized water.
3. Intermediate reference solution 2 (10 μg/mL each of methadone and EDDP). Dilute 1.0 mL of a stock reference solution to 100.0 mL with deionized water.
4. Calibrators in urine. Add appropriate volumes of an intermediate reference solution 1 (100 μg/mL) or 2 (10 μg/mL) to the corresponding appropriate volumes of drug-free urine to provide calibrators with concentrations of 100, 500, 1000, and 5000 ng/mL each of methadone and EDDP. For routine use, one (500 ng/mL) or two (100 and 500 ng/mL) calibrators is adequate.
5. Stock EDDP-D_3 internal standard, 50 μg/mL. Quantitatively, transfer 0.005 g of EDDP-D_3 (Cerilliant) to a 100-mL volumetric flask. Dissolve in about 10 mL of methanol and dilute to volume with deionized water.
6. Working internal standards. Mix 1 mL of methadone-D_3 (100 μg/mL of methanol; Cerilliant) and 3 mL of EDDP-D_3 stock internal standard.

Procedure

1. Transfer 5.0 mL of urine (patient's, calibrator, or control) to labeled Toxi-Tube A extraction tubes (Varian, Lake Forest, CA.).
2. Add 100 μL of working internal standard solution.
3. Mix by inversion for 1 minute.
4. Centrifuge at 1000 ×*g* for 2 minutes.
5. Transfer the organic layer to a prelabeled 5-mL conical centrifuge tube and evaporate to dryness under a stream of air at 60 °C.
6. Reconstitute with 100 μL of ethyl acetate, transfer to an autosampler vial, and inject 1 μL into the GC-MS.

Interpretation

Characteristic ions monitored are 262, 276, and 277 (EDDP); 265, 279, and 280 (EDDP-D_3); 223 and 294 (methadone); and 226 and 297 (methadone-D_3). Positive identification requires qualifier ion ratios at appropriate retention times to be within 20% of those for calibrators. Approximate retention times are 7.4 minutes for EDDP and EDDP-D_3 and 7.8 minutes for methadone and methadone-D_3. For quantitation, the ion ratios 277:280 (EDDP) and 294:297 (methadone) are compared with those for calibrators. Slight thermal conversion of methadone (10,000 ng/mL) to EDDP (53 ng/mL) has been reported when the injector port temperature is 180 °C.

METHOD 34-23 Determination of Norpropoxyphene in Urine by Gas Chromatography-Mass Spectrometry

Principle

An aliquot of a urine specimen that has tested positive for propoxyphene by immunoassay is treated with alkali to convert norpropoxyphene to norpropoxyphene amide. After liquid-liquid extraction, the organic extract is evaporated to dryness; the residue is dissolved in ethyl acetate and then analyzed by selected ion monitoring. Norpropoxyphene-D_5 is used as the internal standard. For norpropoxyphene, the selected ions are 178, 220, and 234 amu, whereas those for norpropoxyphene-D_5 are 183, 235, and 239 amu.

Instrumentation

A gas chromatograph-mass spectrometer equipped with a capillary column (e.g., 25 m × 0.2 mm ID, 0.33-μm film thickness; J & W Scientific Ultra 2) is required for analysis. The operating conditions with this column for splitless sample injection are injection port, 250 °C; detector, 315 °C; initial temperature, 125 °C (0.5 minutes); temperature program, 30 °C/min; final temperature, 280 °C (3.8 minutes); carrier gas, He; pressure programmed to maintain a constant flow of 0.9 mL/min.

Reagents

1. Norpropoxyphene stock reference solution, 1.0 mg/mL. Quantitatively, transfer 0.0136 g of norpropoxyphene maleate (Sigma-Aldrich Chemical Co., St. Louis, MO) to a 10-mL volumetric flask. Dissolve in and dilute to the mark with methanol. Store at −10 °C to −20 °C.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 34-23 Determination of Norpropoxyphene in Urine by Gas Chromatography-Mass Spectrometry—cont'd

2. Norpropoxyphene intermediate reference solution, 100 µg/mL. Dilute 1.0 mL of a stock reference solution (1.0 mg/mL) to 10.0 mL with deionized water.
3. Norpropoxyphene calibrators in urine. Combine an appropriate volume of a stock or intermediate reference solution with an appropriate volume of drug-free urine to provide norpropoxyphene concentrations of 500, 5000, 10,000, and 20,000 ng/mL. For routine use, one (10,000 ng/mL) or two (500 and 10,000 ng/mL) calibrators is adequate.
4. Norpropoxyphene-D_5 internal standard, 25 µg/mL. Dilute 1.0 mL of stock norpropoxyphene-D_5 maleate (100 µg/mL; Cerilliant, Round Rock, TX.) to 4 mL with methanol. Store refrigerated.

Procedure

1. Transfer 1.0 mL of patient's and/or subject's urine, calibrator, or control into separate labeled 16 × 125-mm screw-capped test tubes.
2. Add 100 µL of an internal standard and 1 drop of sodium hydroxide solution (60 g/100 mL).
3. Cap, vortex mix, and let stand for 5 minutes at room temperature.
4. Transfer the samples into separate, labeled Toxi-Tube A extraction tubes (Varian, Lake Forest, Calif.); fill to the 5 mL mark with deionized water and mix by inversion for 1 minute.
5. Centrifuge at 1000 ×*g* for 2 minutes and transfer the organic layer to a 5-mL conical centrifuge tube.
6. Evaporate to dryness at 60 °C under a stream of nitrogen.
7. Reconstitute with 100 µL of ethyl acetate and inject 1 µL into the gas chromatograph-mass spectrometer.

Interpretation

Norpropoxyphene generally produces three peaks during gas chromatographic analysis. Norpropoxyphene undergoes base-catalyzed rearrangement to norpropoxyphene amide that has good gas chromatographic characteristics, resulting in a single symmetrical peak. Identification of norpropoxyphene is based on qualifier ion ratios (178:234 and 220:234 amu) within 20% of those for the calibrators and a retention time within 0.05 minute of the internal standard (~8 minutes). Quantitation is based on a comparison of the ion ratio (234:239 amu) for the unknown with that for the calibrators.

METHOD 34-24 Determination of PCP in Urine by Gas Chromatography-Mass Spectrometry

Principle

A urine specimen that has tested positive for PCP by immunoassay is subjected to liquid-liquid extraction. The organic extract is evaporated, reconstituted with ethyl acetate, and then analyzed by selected ion-monitoring GC-MS, using PCP-D_5 as the internal standard.

Instrumentation

A GC-MS equipped with a capillary column (e.g., 25 m × 0.2 mm ID, 0.33-µm film thickness; J & W Scientific Ultra 2) is required for analysis. The operating conditions with this column for splitless sample injection are injection port, 150 °C; detector, 315 °C; initial temperature, 50 °C; temperature program, 35 °C/min to 280 °C (hold 1.2 minutes); carrier gas, He; pressure programmed to maintain a constant flow of 0.9 mL/min.

Reagents

1. PCP stock calibrator, 1.0 mg/mL. Quantitatively, transfer 11.5 mg of PCP HCl (Sigma-Aldrich Chemical Co., St. Louis) to a 10-mL volumetric flask. Dissolve in and dilute to volume with methanol.
2. PCP intermediate stock calibrator, 10 µg/mL. Quantitatively, transfer 0.5 mL of PCP stock calibrator to a 50-mL volumetric flask and dilute to volume with methanol.
3. PCP calibrators in urine. Transfer 0.125, 0.250, 0.50, 1.0, and 2.0 mL of PCP intermediate stock calibrator (10 µg/mL) to a separate 50-mL volumetric flask. Dilute to volume with PCP-negative urine to provide calibrators with 25, 50, 100, 200, and 400 ng/mL of PCP. For routine use, one (50 ng/mL) or two (25 and 100 ng/mL) calibrators is adequate.
4. Internal standard, PCP-D_5, 2 µg/mL. Quantitatively, transfer 0.2 mL of PCP-D_5 (100 µg/mL; Cerilliant, Round Rock, TX.) to a 10-mL volumetric flask; dilute to volume with methanol.

Procedure

1. Add 5 mL of the patient's urine specimen, control, or calibrator to separate, labeled Toxi-Tube A extraction tubes (Varian, Lake Forest, CA.).
2. Add 100 µL of an internal standard, cap, and mix by gentle inversion for ~1 minute.
3. Centrifuge for 5 minutes (1000 ×*g*).
4. Transfer the organic layer (upper) to a 5-mL disposable centrifuge tube (Kimble No. 73790, Fisher Scientific Co., Pittsburgh, PA) and evaporate just to dryness at ≤30 °C under a gentle stream of air.
5. Reconstitute with 100 µL of ethyl acetate, mix, transfer to an autosampler vial, and inject 1 µL into the GC-MS.

Interpretation

Characteristic ions selected for monitoring are 200, 242, and 186 amu for PCP and 205, 246, and 190 amu for PCP-D_5. For identification, the qualifier ion ratios (242:200 and 186:200 for PCP and 246:205 and 190:205 for PCP-D_5) must agree within 20% of those for calibrators. For quantitation, the area ratio of 200/205 amu is compared with that for calibrators. Approximate retention time under the stated chromatographic conditions is 6 minutes.

APPENDIX 35

Toxic Metals

Thomas P. Moyer, Ph.D., Mary F. Burritt, Ph.D., and John Butz, B.A.

LIST OF METHODS

Method 35-1. Determination of Aluminum in Serum

Method 35-2. Determination of Arsenic in Urine

Method 35-3. Determination of Lead in Whole Blood

Method 35-4. Determination of Mercury in Biological Specimens

Method 35-5. Determination of Selenium in Serum

METHOD 35-1 Determination of Aluminum in Serum

Principle

Serum that represents calibrators, controls, or patient specimens is mixed with dilute acid containing gallium as an internal standard and aspirated directly into an argon plasma. The aerosol is ionized in the plasma and directed through an orifice into a quadrupole mass spectrometer. Mass response from the argon plasma is monitored for aluminum (27 m/z) and gallium (69 m/z). A calibration relationship is created from the height of the mass intensity less baseline counts. A major interference from boron oxide ($^{11}B^{16}O$) must be recognized. Mass resolution must also be programmed to minimize isobaric interferences at masses 26 and 28 from $^{12}C^{14}N$, ^{26}Mg, $^{12}C^{16}O$, ^{28}Si, and $^{14}N^{14}N$.

Instrumentation

An inductively coupled plasma/mass spectrometer (ICP/MS) capable of rapidly monitoring selected ion masses (peak hopping) and capable of internal standard calculations is required for analysis. Mass response from the argon plasma is monitored for the isotope of aluminum (27 m/z), gallium (69 m/z). The use of an ICP/MS equipped with a collision or reaction cell may reduce background signal and facilitate ease of analysis.

Reagents

1. Hydrochloric acid used in all reagent preparations must be ultrapure subboiling redistilled, or trace metals grade.
2. All solid reagents are high purity quality (higher purity than ACS grade).
3. All water used in reagent preparation is triple distilled water (higher purity than type I water).
4. The sample diluent is 50 ug/L gallium in 1% hydrochloric acid prepared from metal shot.
5. Calibrators are prepared in 1% hydrochloric acid to contain aluminum at concentrations of 0, 1, 5, 50, and 100 µg/L.
6. The control sample is a commercially available urine control (BioRad or UTAK Laboratories). Two concentrations of control with nominal values 100 and 250 µg/L are used.
7. The ICP/MS autosampler rinse solution is 1% hydrochloric acid.
8. High purity argon is required to maintain the plasma.
9. Plasma obtained from Transfusion Medicine with low aluminum content is used for preparing calibration samples.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 35-1 Determination of Aluminum in Serum—cont'd

Supplies

Polypropylene pipette tips, specimen cups, and Teflon reagent storage bottles are required. Before use, they are leached in 10% nitric acid for 1 week and rinsed in triple-distilled water.

Procedure

1. The first sample analyzed is a reagent blank. This sample consists of 0.250 mL of water, 0.250 mL of zero calibrator, plus 2.000 mL of diluent.
2. Calibrating solutions are made by mixing 0.250 mL of each calibrator (including the zero calibrator) with 0.250 mL plasma matrix, and 2.000 mL of diluent.
3. The control pool and patient specimens are prepared for analysis by mixing 0.250 mL of each sample with 0.250 mL zero calibrator and 2.000 mL of diluent.
4. The ICP/MS is programmed with the following conditions; these conditions will vary depending on the condition and model of the instrument:

Parameter	Minimum	Maximum
Running Vacuum (torr)	2.42×10^{-5}	
Plasma Power (watts)	1000	1500
Nebulizer (L/min)	0.8	1.0
Dwell Time (ms)	100	500
Sweeps	3	N/A
Replicates	1	N/A
Flush Delay (sec)	20	N/A
Rinse Time (sec)	30	N/A
Aluminum Peak Width (amu)	0.450	0.650

Record the mass abundance of 27 and 69 m/z for each blank, calibrator, control, and specimen. Repeat the analysis at an appropriate dilution for any specimen with a mass abundance greater than the 100 µg/L aluminum calibrator.

Calculation

1. The instrument software should be programmed to subtract the mean of the reagent blank intensity from each specimen raw intensity.
2. The instrument software will generate a calibration curve based on the intensity ratios of aluminum to gallium by creating a regression equation. The regression constant of this equation should be >0.999.
3. Aluminum concentrations of specimens are calculated from the intensity ratios of the specimens compared to the calibration curve.

Reference

Burritt MF, Butz JA modified from Forrer R, Guatschi K, Lutz H. Simultaneous measurement of trace element Al, As, B, Be, Cd, Co, Cu, Fe, Li, Mn, Mo, Ni, Rb, Se, Sr, and Zn in human serum and their reference ranges by ICP-MS. Biological Trace Element Research 2001;80:77-93.

METHOD 35-2 Determination of Arsenic in Urine

Principle

Urine-based calibrators, controls, or patient specimens are mixed with dilute acid containing gallium as an internal standard and aspirated directly into the argon plasma. The aerosol is ionized in the plasma and directed through an orifice into a quadrupole mass spectrometer. Mass response from the argon plasma is monitored for As (75 m/z), gallium (69 m/z), and $^{16}O^{35}Cl$ (51 m/z) to facilitate correction for $^{40}Ar^{35}Cl$ (75 m/z) interference. A calibration relationship is created from the height of the mass intensity less baseline counts.

It is important to note that the instrument response in biological matrices will differ from that in an aqueous matrix. Therefore the samples, controls, and calibrators must be diluted to have an equivalent matrix. Failure to account for matrix effects can lead to erroneous results.

Unlike most metals, As possesses a relatively high first ionization potential (9.81 eV) and is not fully ionized by an argon plasma. The diluent must contain a carbon source, such as an alcohol or Triton-X 100 to promote ionization.

Instrumentation

An ICP/MS capable of rapidly monitoring selected ion masses (peak hopping) and capable of internal standard calculations is required for analysis. Mass response from the argon plasma is monitored for the isotope of As (75 m/z), gallium (69 m/z), and $^{16}O^{35}Cl$ (51 m/z) to calculate the correction factor for the $^{40}Ar^{35}Cl$ interference.

Reagents

1. Hydrochloric acid used in all reagent preparations must be ultrapure subboiling redistilled, or trace metals grade.
2. All solid reagents are high purity quality (higher purity than ACS grade).
3. All water used in reagent preparation is triple-distilled water (higher purity than type I water).
4. Tertiary butyl alcohol (Fisher Scientific).
5. The sample diluent is 25 mL/L t-butanol plus 50 µg/L gallium in 2% hydrochloric acid.
6. Calibrators are prepared in 2% hydrochloric acid to contain As concentrations of 0, 5, 10, 50, 100, and 500 µg/L.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 35-2 Determination of Arsenic in Urine—cont'd

7. The control material is a commercial urine control (BioRad or UTAK Laboratories). Two concentrations of control of with nominal values 100 and 250 ug/L are used.
8. The ICP/MS autosampler rinse solution is 1% hydrochloric acid.
9. High purity argon is required to maintain the plasma.

Supplies

Sarstedt 12 × 75 mm polypropylene tubes and Teflon reagent storage bottles are required. Before use, reagent bottles are leached in 10% nitric acid for 1 week and rinsed in triple-distilled water.

Procedure

1. The first sample analyzed is a reagent blank. This sample consists of 0.30 mL of water, 0.30 mL of zero calibrator, plus 2.450 mL of diluent.
2. Calibrating solutions are made by mixing 0.30 mL of each calibrator (including the zero calibrator) with 0.30 mL serum matrix, and 2.40 mL of diluent.
3. The control pool and patient specimens are prepared for analysis by mixing 0.30 mL of each sample with 0.30 mL zero calibrator and 2.40 mL of diluent.
4. The ICP/MS is programmed with the following conditions; these conditions will vary depending on the condition and model of the instrument:

Parameter	Minimum	Maximum
Running Vacuum (torr)	2.42×10^{-5}	
Plasma Power (watts)	1100	1500
Nebulizer (L/min)	0.8	1.0
Dwell Time (ms)	100	500
Sweeps	3	N/A
Replicates	1	N/A
Flush Delay (sec)	20	N/A
Rinse Time (sec)	30	N/A

Record the mass abundance of 69, 75, and 51 m/z for each blank, calibrator, control, and specimen. Repeat the analysis at an appropriate dilution for any specimen with a mass abundance greater than the 500 μg/dL As calibrator.

Calculation

1. The instrument software should be programmed to subtract the mean of the reagent blank intensity and the correction of $^{40}Ar^{35}Cl$ from each specimen raw intensity.
2. The instrument software will generate a calibration curve based on the intensity ratios of arsenic to gallium by creating a regression equation. The regression constant of this equation should be >0.999.
3. Arsenic concentrations of specimens are calculated from the intensity ratios of the specimens compared with the calibration curve.

METHOD 35-3 Determination of Lead in Whole Blood

Principle

Lead can be readily analyzed on an ICP/MS. Aqueous acidic calibrating standards are diluted with an acid containing two internal standards. Quality control and patient samples are also diluted in an identical manner. All diluted samples are aspirated into a pneumatic nebulizer and the resulting aerosol directed to the hot plasma discharge by a flow of argon. In the annular plasma the aerosol is vaporized, atomized, then ionized. The ionized gasses plus neutral species formed in the annular plasma space are aspirated from the plasma through an orifice into a quadruple mass spectrometer. The mass range from 1 to 263 amu is rapidly scanned multiple times and ion counts tabulated for each mass of interest. Instrumentation response is defined by the linear relationship of analyte concentration versus ion count (analyte ion count/internal standard ion count). Analyte concentrations are derived by reading the ion count ratio for each mass of interest and determining the concentration.

Instrumentation

An ICP/MS capable of rapidly monitoring selected ion masses (peak hopping) and capable of internal standard calculations is required for analysis. Mass response from the argon plasma is monitored for sum of the major isotopes of Pb (206, 207, 208 m/z) and bismuth (209 m/z). There are no interferences at these masses. It is essential that all three major isotopes of Pb be summed because of the naturally occurring local isotopic variation that is unique to Pb.

Reagents

1. Hydrochloric acid used in all reagent preparations must be ultrapure subboiling redistilled, or trace metals grade.
2. All solid reagents are high purity quality (higher purity than ACS grade).
3. All water used in reagent preparation is triple-distilled water (higher purity than type I water).

Continued.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

METHOD 35-3 Determination of Lead in Whole Blood—cont'd

4. The sample diluent is 50 μg/L bismuth in 2% hydrochloric acid (prepared from metal shot).
5. Calibrators are prepared in 2% hydrochloric acid to contain Pb at concentrations of 0, 1, 10, 20, 50, and 100 μg/dL Pb (prepared from metal shot).
6. Controls. The control material is a commercial whole blood control (BioRad or UTAK Laboratories). Three concentrations of control with nominal values 10, 30, and 60 μg/dL are used.
7. The ICP/MS autosampler rinse solution is 2% hydrochloric acid.
8. High purity argon is required to maintain the plasma.

Supplies

Sarstedt 12 × 75 mm polypropylene tubes and Teflon reagent storage bottles are required. Before use, reagent bottles are leached in 10% nitric acid for 1 week and rinsed in triple-distilled water.

Procedure

1. The first sample analyzed is a reagent blank. This sample consists of 0.05 mL zero calibrator, plus 2.45 mL of diluent.
2. Calibrating solutions are made by mixing 0.05 mL of each calibrator (including the zero calibrator) with 2.45 mL of diluent.
3. The control pool and patient specimens are prepared for analysis by mixing 0.05 mL of each sample with 2.45 mL of diluent.
4. The ICP/MS is programmed with the following conditions; these conditions will vary depending on the condition and model of the instrument:

Parameter	Minimum	Maximum
Running Vacuum (torr)	2.42×10^{-5}	
Plasma Power (watts)	800	1500
Nebulizer (L/min)	0.7	1.2
Dwell Time (ms)	100	500
Sweeps	3	N/A
Replicates	1	N/A
Flush Delay (sec)	20	N/A
Rinse Time (sec)	30	N/A

Record the summed mass abundance of 206, 207, and 208 m/z and 209 m/z for each blank, calibrator, control, and specimen. Repeat the analysis at an appropriate dilution for any specimen with a mass abundance greater than the 100 μg/dL Pb calibrator.

Calculation

1. The instrument software should be programmed to subtract the mean of the reagent blank intensity from each specimen raw intensity.
2. The instrument software will generate a calibration curve based on the intensity ratios of Pb to bismuth by creating a regression equation. The regression constant of this equation should be >0.999.
3. Lead concentrations of specimens are calculated from the intensity ratios of the specimens compared with the calibration curve.
4. Samples greater than 9 μg/dL must be repeated to confirm the results are not spurious because of contamination during processing.

METHOD 35-4 Determination of Mercury in Biological Specimens

Principle

Mercury is quantified by ICP/MS. Urine or blood-based calibrators, controls, or patient specimens are mixed with dilute acid containing bismuth as an internal standard and aspirated directly into the argon plasma. Mass response from the argon plasma is monitored for the sum of the major isotopes of Hg (199, 200, 201, and 202 m/z) and bismuth (209 m/z). A calibration relationship is created from the height of the mass intensity less baseline counts. There are no significant interferences for Hg.

It is important to note that the instrument response in biological matrices will differ from that in an aqueous matrix. Therefore the samples, controls, and calibrators must be diluted to have an equivalent matrix. Failure to account for matrix effects can result in erroneous results.

Mercury presents a unique analytical challenge because of its instability and adherence to the ICP/MS parts in direct contact with the sample. A chemical additive such as gold or potassium dichromate must be added to the reagents to eliminate carryover, high background signal, and spiking signal. Properly executed, this method will allow Hg analysis without sample digestion.

Instrumentation

An ICP/MS capable of rapidly monitoring selected ion masses (peak hopping) and capable of internal standard calculations is required for analysis.

METHOD 35-4 Determination of Mercury in Biological Specimens—cont'd

Reagents

1. Hydrochloric acid used in all reagent preparations must be ultrapure subboiling redistilled, or trace metals grade.
2. All solid reagents are high purity quality (higher purity than ACS grade).
3. All water used in reagent preparation is triple-distilled water (higher purity than type I water).
4. The sample diluent is 50 μg/L bismuth and 1 mg/L gold in 2% hydrochloric acid (prepared from bismuth shot or elemental gold).
5. Calibrators are prepared in 2% hydrochloric acid to contain Hg at concentrations of 1, 5, 10, and 50 μg/L.
6. The control sample is a commercially available urine control (BioRad or UTAK Laboratories). Two concentrations of control with nominal values 100 and 250 μg/L are used. The ICP/MS autosampler rinse solution is 2% hydrochloric acid.
7. High purity argon is required to maintain the plasma.

Supplies

Polypropylene pipette tips, specimen cups, and Teflon reagent storage bottles are required. Before use, they are leached in 10% nitric acid for 1 week and rinsed in triple-distilled water.

Procedure

1. The first four samples analyzed are reagent blanks. These samples consist of 0.60 mL of water plus 2.40 mL of diluent. This is to flush residual Hg from the aerosol chamber from previous sample analysis.
2. Calibrating solutions are made by mixing 0.30 mL of each calibrator (including the zero calibrator) with 0.30 mL urine matrix, and 2.40 mL of diluent.
3. The control pool and patient specimens are prepared for analysis by mixing 0.30 mL of each sample with 2.40 mL of diluent.
4. The ICP/MS is programmed with the following conditions; these conditions will vary depending on the condition and model of the instrument:

Parameter	Minimum	Maximum
Running Vacuum (torr)	2.42×10^{-5}	
Plasma Power (watts)	1100	1500
Nebulizer (L/min)	0.8	1.0
Dwell Time (ms)	100	500
Sweeps	3	N/A
Replicates	1	N/A
Flush Delay (sec)	20	N/A
Rinse Time (sec)	30	N/A

Record the summed mass abundance of 199, 200, 201, and 202 m/z and 209 m/z for each blank, calibrator, control, and specimen. Repeat the analysis at an appropriate dilution for any specimen with a mass abundance greater than the 50 μg/L Hg calibrator.

Calculation

1. The instrument software should be programmed to subtract the mean of the reagent blank intensity from each specimen's raw intensity.
2. The instrument software will generate a calibration curve based on the intensity ratios of Hg to bismuth by creating a regression equation. The regression constant of this equation should be >0.999.
3. Mercury concentrations of specimens are calculated from the intensity ratios of the specimens compared with the calibration curve.

METHOD 35-5 Determination of Selenium in Serum

Principle

Urine-based calibrators, controls, or patient specimens are mixed with dilute acid containing 2.5% tertiary butyl alcohol for signal enhancement and yttrium internal standard and aspirated directly into the argon plasma. Mass response from the argon plasma is monitored for selenium (78, 82 m/z), yttrium internal standard (69 m/z), bromine (79, 81 m/z), krypton (83 m/z), and gadolinium (158 m/z) to monitor for potential interference. Samples containing high concentrations of bromine will form $^{81}Br^{1}H$ interfering with ^{82}Se. Krypton is sometimes present in low-quality argon; both ^{78}Kr and ^{82}Kr interfere with selenium. Patients recently receiving radiation sensitizers containing gadolinium will have high concentrations of ^{158}Gd, which interferes as the doubly charged ion Gd^{++} (78 m/z).

It is important to note that the instrument response in biological matrices will differ from that in an aqueous matrix. Therefore the samples, controls, and calibrators must be diluted with an equivalent matrix. Failure to account for matrix effects can lead to erroneous results.

Unlike most metals, selenium possesses a relatively high first ionization potential (9.75 eV) and is not fully ionized by an argon plasma. Thus the diluent must contain a carbon source to promote ionization, such as an alcohol or Triton-X 100. Operating the plasma at a higher wattage than what is typical for most analysis is also advisable.

Instrumentation

An ICP/MS capable of rapidly monitoring selected ion masses (peak hopping) and capable of internal standard calculations is required for analysis. Mass response from the argon plasma is monitored for two isotopes of selenium (78, 82 m/z), yttrium (89 m/z), bromine (79, 81 m/z), krypton (83 m/z), and gadolinium (158 m/z). Unless a reaction cell or collision cell is employed, the major isotope of selenium (80 m/z) is inaccessible because of interference from the argon dimer formed in abundance in the plasma, $^{40}Ar^{40}Ar$ (80 m/z). However, such instrumentation is not necessary as human selenium

METHOD 35-5 Determination of Selenium in Serum—cont'd

concentrations are high enough that monitoring ^{78}Se and ^{82}Se produces sufficient sensitivity.

Reagents

1. Nitric acid used in all reagent preparations must be ultrapure subboiling redistilled, or trace metals grade.
2. All solid reagents are high purity quality (higher purity than ACS grade).
3. All water used in reagent preparation is triple-distilled water (higher purity than type I water).
4. Tertiary butyl alcohol is from Fisher Scientific.
5. The sample diluent is 50 μg/L gallium and 25 mL/L t-butanol in 2% nitric acid.
6. Calibrators are prepared in 1% nitric acid to contain selenium at concentrations of 0, 1, 5, 50, and 100 μg/L.
7. The control sample is a commercially available urine control (Biorad, UTAK Laboratories). Two concentrations of control with nominal values 100 and 200 μg/L are used.
8. The ICP/MS autosampler rinse solution is 2% nitric acid.
9. Urine matrix from a representative human donor pool.
10. High purity argon is required to maintain the plasma.

Supplies

Sarstedt 12 × 75 mm polypropylene tubes and Teflon reagent storage bottles are required. Before use, reagent bottles are leached in 10% nitric acid for 1 week and rinsed in triple distilled water.

Procedure

1. The first specimen analyzed is a reagent blank. This sample consists of 0.10 mL of water, 0.10 mL 0 standard, and 1.80 mL of diluent.
2. Calibrating solutions are made by mixing 0.10 mL of each calibrator with 0.10 mL urine matrix, and 1.80 mL of diluent.
3. The control pool and patient specimens are prepared for analysis by mixing 0.10 mL of each sample with 0.10 mL 0 standard, and 1.80 mL of diluent.
4. The ICP/MS is programmed with the following conditions, which may vary depending on the condition and model of the instrument:

Parameter	Minimum	Maximum
Running Vacuum (torr)	2.42×10^{-5}	
Plasma Power (watts)	1250	1500
Nebulizer (L/min)	0.8	1.0
Dwell Time (ms)	100	500
Sweeps	3	N/A
Replicates	1	N/A
Flush Delay (sec)	20	N/A
Rinse Time (sec)	30	N/A

Record the mass abundance of 78, 82, and m/z for each blank, calibrator, control, and specimen. Repeat the analysis at an appropriate dilution for any specimen with a mass abundance greater than the 200 μg/L selenium calibrator.

Calculation

1. The instrument software should be programmed to subtract the mean of the reagent blank intensity from each specimen's raw intensity.
2. The instrument software will generate a calibration curve based on the intensity ratios of selenium to yttrium by creating a regression equation. The regression constant of this equation should be >0.999.
3. Selenium concentrations of specimens are calculated from the intensity ratios of the specimens compared with the calibration curve.

CALCULATING INDIVIDUALIZED PATIENT-SPECIFIC RISKS USING BIOCHEMICAL MEASUREMENTS[150A]*

Calculating an individualized risk (patient-specific risk) for any given condition is accomplished by multiplying the a priori risk for that condition by a likelihood ratio that is calculated using the woman's analyte measurements (i.e., patient risk = a priori risk × likelihood ratio). This basic equation is used to calculate patient-specific risk for neural tube defects, Down syndrome, trisomy 18, or any other condition in which the distributions of tests for the unaffected and affected population have been defined. The a priori risk is obtained from large epidemiological studies that ascertain the prevalence for the condition under consideration. For example, a woman's age is used to define her a priori risk for having a fetus with Down syndrome. The likelihood ratio is determined by calculating the ratio of the height of the affected and unaffected overlapping population distributions for any specified multiple of the median (MoM) value. When multiple tests are used, a single likelihood ratio is calculated using the overlapping distributions for each test but with the correlation between the tests taken into account. Alpha fetoprotein (AFP) as a single test for Down's syndrome is discussed below to demonstrate the principle of how individualized risks are calculated.

Risk Based on Maternal Age Alone

The first step in calculating an individualized risk for Down's syndrome is to determine the woman's risk based on her age using the well-known increase in the birth prevalence of Down's syndrome as maternal age advances (see Figure 54-4 in Chapter 54 of the 4th edition of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*). The maternal age is defined as the age at the expected date of delivery. In practice the age-specific risk is determined using an equation that has been fitted to the age-prevalence curve rather than taken from a table of risks. A number of age-specific equations have been published that differ slightly, but overall give comparable risks.[91A,160A,225A] A recently published equation[160A] for calculating risk at term is $p = 0.0006345 + e^{(-16.08695+0.2852891\times MA)}$, where the risk of Down syndrome is $1:(1-p)/p$, and MA is the maternal age at delivery in completed years. If decimal years are used, 0.5 year is subtracted from the age before using the equation (e.g., for a decimal age of 35.5 years use 35.0). Age-specific risks can be expressed as either risk at term or in the second trimester when screening is accomplished. Second trimester risks are higher than term risk because an estimated 23% of Down syndrome fetuses are spontaneously aborted from second trimester to term.[86] Second trimester risks are calculated by multiplying the right hand side of the calculated odds by 0.77 (the third trimester fetal loss coefficient for Down syndrome). For example, if the term odds calculated from the equation is 1:750, then the second trimester odds are 1:577. The equation is valid between 15 and 50 years.

Calculation of a Likelihood Ratio

The next step in calculating a patient-specific risk is to determine the likelihood ratio. In essence the likelihood ratio is the relative increase, decrease, or no change in the prior risk based on the woman's analyte measurements. The process of computing a likelihood ratio can be visualized by examining the overlapping distributions of maternal serum AFP measurements from women with a normal pregnancy and women with a Down syndrome pregnancy. Figure A54-1 displays these distributions when results are expressed as MoM. Vertical lines have been arbitrarily drawn at 0.5 and 0.83

*References are found in Ch. 54 of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics,* edition 4.

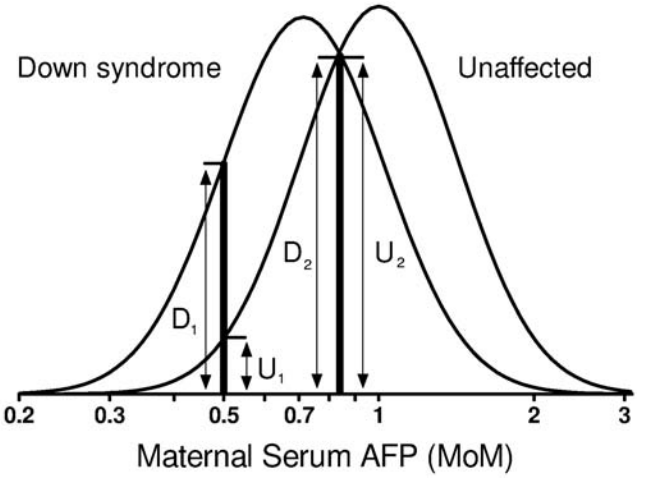

Figure A54-1 Calculating individual Down syndrome risks at two AFP levels below 1.0 MoM. At an AFP value of 0.50 MoM, the likelihood ratio is defined by the height of a line drawn to its point of intersection with the AFP population distribution curve for Down syndrome pregnancies (D_1), divided by the height of the line drawn to its point of intersection with the population distribution curve for unaffected pregnancies (U_1). In this case, D_1 is 2.2 times higher than U_1, so the likelihood ratio is 2.2. At an AFP value of 0.83 MoM, the likelihood ratio is 1.0. At this point, the curves of unaffected and affected AFP population distributions cross ($D_2/U_2 = 1.0$), and the revised risk would be no different from the age-associated risk. Any AFP value below 0.83 MoM is associated with increased risk, and any AFP value above 0.83 MoM is associated with decreased risk for Down syndrome.

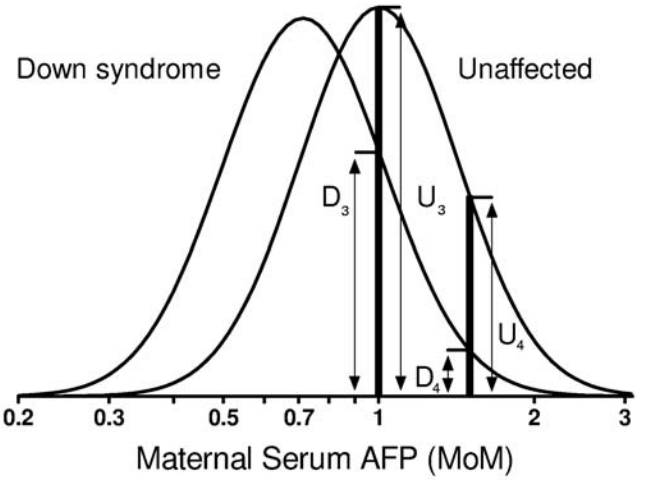

Figure A54-2 Calculating individual Down syndrome risks at two AFP levels above 0.83 MoM. At an AFP value of 1.00 MoM, the likelihood ratio is defined by the height of a line drawn to its point of intersection with the AFP population distribution curve for Down syndrome pregnancies (D_3) divided by the height of the line drawn to its point of intersection with the population distribution curve for unaffected pregnancies (U_3). An AFP MoM of 1.00 is an "average" or "normal" result. This result actually reduces the risk for Down syndrome slightly, since the likelihood ratio is 0.80 ($D_3/U_3 = 0.80$). At an AFP value of 1.80 MoM, the likelihood ratio is 0.38 (D_4/U_4).

MoM. The median AFP value for Down syndrome pregnancies is 0.75 MoM, indicating that values are lower by about 25% as compared with unaffected pregnancies (centered at 1.0 MoM). At an AFP value of 0.5 MoM, the likelihood ratio is defined by the height of the line drawn to the point of intersection with the AFP population distribution curve for Down syndrome pregnancies (D_1), divided by the height of the line drawn to its point of intersection with the population distribution curve for unaffected pregnancies (U_1). In this case D_1 is 4.2 times higher than U_1, so the likelihood ratio is 4.2. This can be interpreted as follows: a woman with a value of 0.5 MoM is 4.2 times more likely to be carrying a baby with Down syndrome as compared with her risk based on age alone. At an AFP value of 0.84, the likelihood ratio is 1.0, because at this value the curves cross and the height of the two curves is identical ($D_2/U_2 = 1.0$). Thus any MoM value below 0.84 results in increased risk, and any MoM value above 0.84 will decrease risk.

Figure A54-2 displays the same overlapping distributions but with vertical lines arbitrarily drawn at 1.0 and 1.8 MoM. An AFP level of 1.0 MoM is the "average" or "normal" result, but this result actually produces a reduction in risk, since the likelihood ratio is 0.63 ($D_3/U_3 = 0.80$). It might seem counterintuitive that an "average" result produces a likelihood ratio <1.0, but only a worthless test would yield a likelihood ratio of 1.0 for an "average" test result. At an AFP MoM of 1.8, the likelihood ratio is 0.23 (D_4/U_4), meaning that a woman with this test result would have her age-related risk reduced by a factor of 0.23. In actual practice, likelihood ratios are computed electronically using a set of statistical parameters that describe the overlapping distributions and the correlations between the tests (if multiple biochemical tests are used). The approach described is, in principle, identical to that used for calculating risk for open spina bifida using the single AFP test, except that the overlapping distributions would be those for unaffected pregnancy and open spina bifida.[329]

Calculation of Patient-Specific Risk

The final patient-specific risk is calculated by multiplying the age-specific risk by the likelihood ratio. For example, consider the risks that would result for a woman who is 35.5 years of age with the four AFP MoM values given in the previous section. Her age-specific second trimester risk is 1:270 (calculated using the risk equation and fetal loss coefficient given above). If her AFP MoM value was 0.5, her likelihood ratio is 4.2 and her final revised risk would be 4.2 times 1:270 times, or 1:64. Her final risks, if she had an AFP MoM value of 0.84, 1.0, or 1.8, would be 1:270 (unchanged from her age risk), 1:430, and 1:1170, respectively.

Estimating a Likelihood Ratio from Multiple Biochemical Measurements

Calculating a patient-specific risk for Down syndrome using multiple biochemical tests is accomplished in the same manner as for a single maker (i.e., the age-specific risk is multiplied by a likelihood ratio). The age-specific risk is calculated in the same manner as for a single test. A single likelihood ratio is then calculated by combining the measurements for all of the tests measured using multivariate overlapping Gaussian distributions. For example, a single test can be visualized as two overlapping "camel humps," but two tests are visualized as overlapping "haystacks." The visualization breaks down with three or more tests.

Consider the example in which AFP, uE_3, and CG have been measured on a maternal serum sample (the triple test). If each of the three biochemical tests were independent predictors of Down syndrome risk, then the combined likelihood ratio would be the product of the three individual likelihood ratios. Figure A54-3 *A, B,* and *C* provides an example of such a calculation, assuming the woman's AFP, uE_3, and CG levels were 0.6, 0.45, and 2.0 MoM, respectively. The product of the three individual likelihood ratios is 81.5 ($2.5 \times 13.0 \times 2.5$). This combined likelihood ratio indicates that the woman's individualized Down syndrome risk is now 81.5 times greater than her age-associated risk. However, the three biochemical tests are not totally independent predictors, but have small pairwise correlations. For that reason, a more refined method of computing the combined likelihood ratio that takes these correlations into account is required. When this is done, the likelihood ratio for the current example is reduced to 17.1. This reduction intuitively makes sense, because the maximum predictive value of the three tests would occur only if there were no correlation between the tests. A similar multivariate Gaussian model is also used to calculate patient-specific risks for trisomy 18.[249]

Other models have been proposed for calculating risks, including logistic regression[333A] and linear discriminant analysis,[239A] and some are occasionally used clinically. All of these models can provide reliable risks, but if not derived or implemented correctly, each can also result in unreliable risk estimates. Discriminant aneuploidy detection or "DAD," a high order nonlinear discriminate function, is an example of an unreliable model and should not be used in its presently published form.[116A]

The Mathematics of Computing Down Syndrome Risk Using Multiple Tests

The mathematical computations necessary for combining maternal age and one (or two) maternal serum analyte measurements to derive an individualized Down syndrome risk estimate are not difficult and can be found in other publications.[116A,271A] However, when three or more serum and/or ultrasound measurements are involved, the computations become far more involved and are beyond the scope of this chapter. One approach for dealing with the complexity of risk calculations for multiple test screening is to purchase

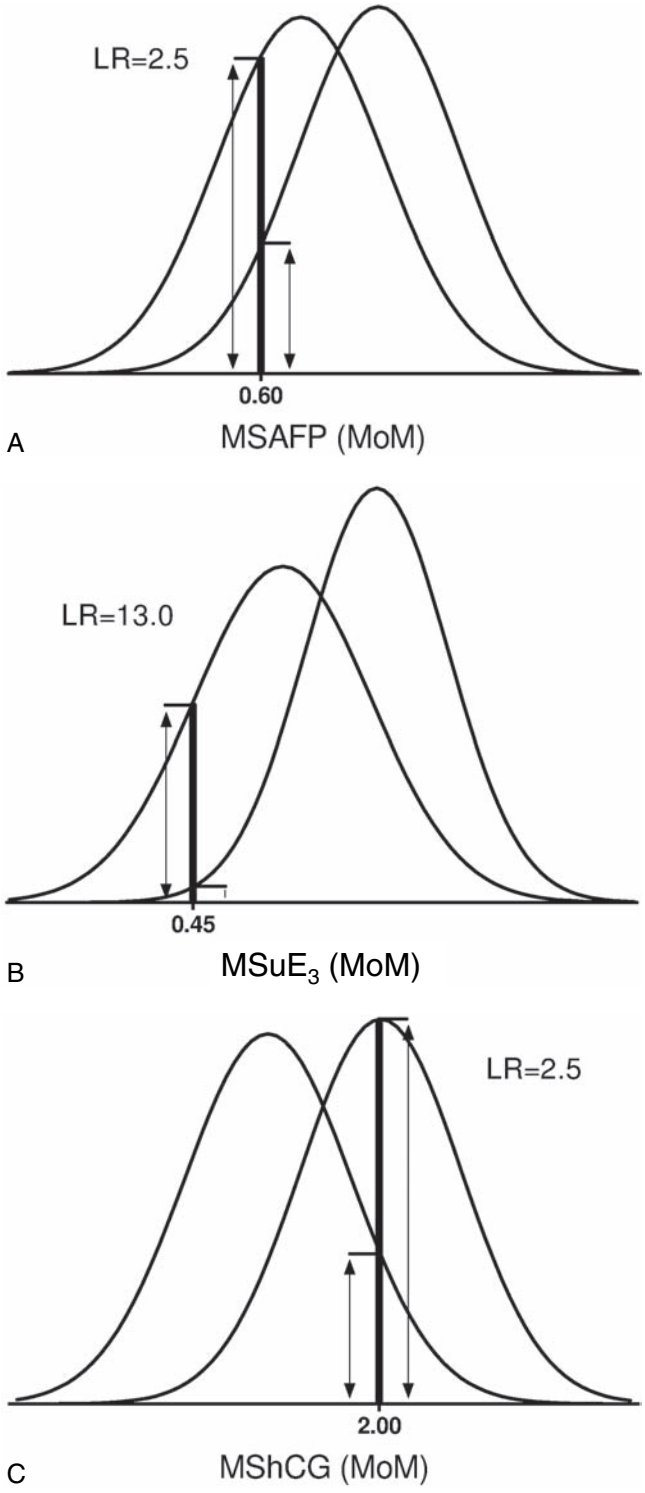

Figure A54-3 Likelihood ratios for AFP, uE_3, and CG measurements of 0.6, 0.4, and 2.0 MoM, respectively, for a hypothetical patient screened using the triple test: **(A)** likelihood ratio for MSAFP at 0.6 MoM, **(B)** likelihood ratio for $MSuE_3$ at 0.45 MoM, and **(C)** likelihood ratio at 2.0 MoM for CG. The products of these three likelihood ratios could be multiplied together to provide an estimate of the combined likelihood ratio if all three markers were completely independent predictors of Down syndrome risk.

commercial software. Use of such software also has the advantage that most packages include an up-to-date patient management system designed for prenatal screening. Almost all commercial (or in-house) software relies on the same algorithm for computing risk (overlapping multivariate Gaussian distributions). However, the software manufacturer usually requires the end user to select from a set of parameters or to provide their own parameters for calculating risk. Parameter sets consist of the logarithmic mean and standard deviations (SDs) for both unaffected and Down syndrome pregnancies for each of the analytes and also pairwise correlation coefficients for both the unaffected and Down syndrome pregnancies. Truncation limits that define the most extreme values to be interpreted for each of the analytes are also necessary. Thus to generate the likelihood ratios for a quadruple test using a single dating method (e.g., pregnancies dated from the last menstrual period), 36 numbers define the parameter set. The size of a parameter set is doubled if separate parameters specific to the method of gestational dating are to be used (ultrasound versus last menstrual period dating). Reliable parameter sets appropriate for the analytes to be used for screening and specific for different methods of gestational dating are difficult to derive and beyond the capability of most laboratories. In practice almost all laboratories rely on published parameter sets. Comprehensive parameter sets are few in number, but the laboratory director is responsible for choosing one that is appropriate for the population being screened. The following discussion provides methods aimed at helping the screening laboratory appreciate the impact of different parameter sets and how they might choose one.

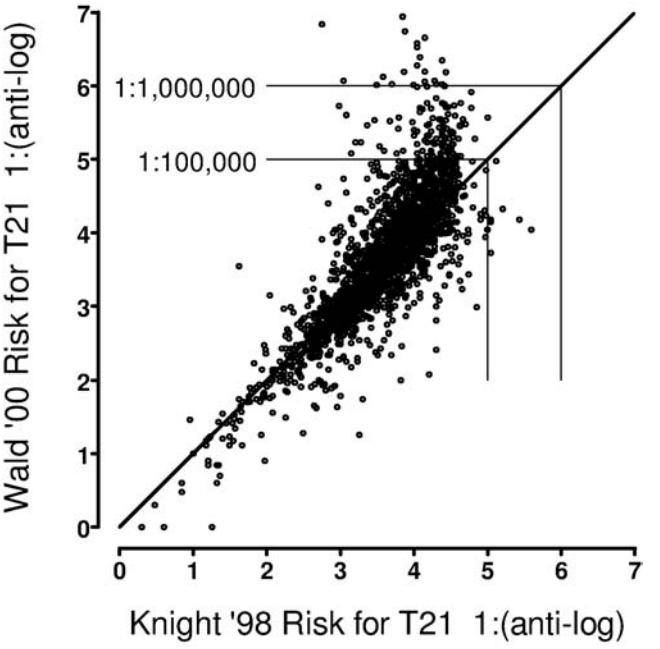

Figure A54-4 A comparison of risks generated by two parameter sets using actual patient MoM values from 3000+ screened women. Y-axis (Wald 00 parameters). X-axis (Knight 98 parameters). Line of identity at 45°. See text for source of Wald and Knight parameters.

What Parameter Sets Are Available?

Data from the Maternal Screening FP Proficiency Testing Survey, jointly sponsored by the Foundation for Blood Research/College of American Pathologists (FBR/CAP), indicates that most screening laboratories in the United States and Canada use one of three parameter sets. These have been designated by the lead author and year of publication. They include Wald 1988,[331] Wald 2000,[332A,332B,333,335A] and Knight 1998.[154,184A] The original parameter set of Wald and his colleagues is based on data collected in Oxford, England. It was published when the methodology for the triple test was first described and is still widely used (Wald 88). Wald and his colleagues have extensively modified and updated this parameter set, and it now includes quadruple tests (Wald 00). The third parameter set (Knight 98) is based on data collected primarily from California laboratories in the mid 1990s,[184A] with later updates for dimeric inhibin A (DIA).[154] The Wald 1988 parameter set is not optimal, and laboratories are being encouraged to use one of the newer sets (Wald 00 or Knight 98).

Differences in Patient-Specific Risks Using Two Different Parameter Sets

How does the laboratory decide which parameter set to implement? The first question to be answered is whether it makes any difference as to which set is chosen. One approach to answering this question is to compare the Down syndrome risks generated by the parameter sets in question using actual patient MoM data generated by a screening program. For example, Figure A54-4 displays the Down syndrome risks generated for more than 3000 women screened using the quadruple test (AFP, estriol (uE_3), CG, and DIA) by the FBR (all had gestational age estimates based on ultrasound dating). On the logarithmic horizontal axis is the Down syndrome risk based on the Knight 98 parameters. On the vertical axis is the Down syndrome risk based on the Wald 00 parameters. The results are highly correlated, and the observations fall, on average, on the line of identity. This indicates that similar risks have been generated by the two parameter sets. However, at very low risks (upper right quadrant), the risks derived from the Wald 00 parameters are slightly lower than the corresponding risks derived from the Knight 98 parameters. This difference is unlikely to have any impact on the screening program because the low risks would be classified as screen negative. At high risks (lower left quadrant), the risks derived from the Wald 00 parameters are higher than the corresponding risks derived from the Knight 98 parameters. This would result in a slightly higher screen-positive rate at any given risk cutoff for the Wald 00 parameters and, most likely, a slightly higher detection rate. A few of the individual observations are different by a factor of 10 or more, indicating that differences between the parameter sets can in some instances result in substantially different risk estimates. These "discrepant" risks generally occur when one (or more) of the four analyte results are in the tails

*On a linear scale.

of their respective distributions (e.g., are univariate or multivariate outliers).

The discrepancy in risks caused by different parameter sets has been observed by screening programs for selected women. Discrepant risks occur with a variety of analyte combinations, and it has not been possible to attribute the cause to a single or a few parameters. However, the above analysis shows that either of the two parameter sets will yield reliable results and essentially equivalent risks over a wide range of analyte results.

Comparing Published Parameters With a Laboratory's Estimate

A second approach to determining whether a parameter set is appropriate is to generate selected parameters using the laboratory's own screening results. Few laboratories will have sufficient data to establish parameters (means, SDs, and correlation coefficients) for Down syndrome pregnancies. However, a comparison between a laboratory's data and published parameter sets restricted to unaffected pregnancies can still provide useful information. Table A54-1 shows how laboratories might compare their in-house parameter estimates for unaffected pregnancies with published ones.

The first row shows the log SDs for AFP MoM results for unaffected pregnancies when dated using the last menstrual period from three published parameter sets along with that same parameter computed using more than 3000 consecutive AFP MoM results from similarly dated pregnancies from a serum screening program in Maine. One way to judge which of the three published SDs are closest to the laboratory's estimate is to compare the ratio of the variances (SD squared). If the two estimates are similar, the ratio should be close to 1.00 (this ratio is usually computed as the ratio of the larger to the smaller variance). The AFP variance ratios for the three parameter sets are 1.82, 1.03, and 1.21, indicating that parameter set 2 is the closest fit. Generally, variance ratios of 1.10 or less indicate reasonable agreement. For this comparison to be reliable, care must be taken in computing the "in-house" estimate of the logarithmic SD. It is not sufficient to simply take the overall SD of the logged analyte values reported in MoM. A robust analytical methodology is described later that can be used by individual laboratories to properly trim and use regression analysis to compute their own SD.

The published and reported correlation coefficients are shown beginning in row five of Table A54-1. Proper comparisons of the correlation coefficients (r values) can be done

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

by first squaring the values. By retaining the sign, the differences between the r-squared values give an indication of "closeness." For example, a value of r = −0.11 squared would be −0.0121. The difference for the AFP and uE_3 r values (row 5 in the table) for parameter set 1 and the observed data would be $(0.130)^2 - (0.286)^2 = 0.0649$. The corresponding differences for sets 2 and 3 are 0.0817 and 0.0233. In our experience, signed differences in r squared of 0.10 or greater can have an important impact on computed risks, especially when the correlation coefficients are small (as in Table A54-1).

Evaluating the truncation limits set by each parameter set (beginning in row 11) is difficult. The wider the limits, the higher (or lower) the likelihood ratios can achieve. The wider limits for parameter set 2 versus 3 are the likely cause of the systematically lower (or higher) risks at the extremes noted in Figure A54-4. The probability plots that each laboratory can create (see section entitled Determining the Log Standard Deviation (SD) for Analyte A) help guide the user in deciding whether truncation limits seem appropriate. For example, consider a laboratory that is examining 1000 AFP measurements among unaffected singleton pregnancies from their screening program. If they were to find a logarithmic SD of 0.1502, the upper truncation limits for the three published parameter sets are at 2.0, 3.5, and 2.0 SDs above the mean. The upper limits for the first and third parameter set are equivalent to the 97.5th percentile, but the third is above the 99.9th percentile. The laboratory can examine the plot and see how well the data fit at the upper limit. Even if the data were to fit in the extreme upper tail, setting the upper truncation limit must also take into account how well the Down syndrome cases fit at high AFP levels as well, and those measurements are systematically lower by about 25%.

It is not possible to provide definitive guidelines as to what action, if any, should be taken if parameters, correlation coefficients, or truncation limits exceed the suggested limits discussed above. Instead the exercise is recommended to ensure that the laboratory is obtaining parameter sets that are in reasonable agreement with those published by experienced screening programs.

A Method to Customize Parameter Sets

One publication contains methodology that allows laboratories to "tailor" or "customize" the parameter set used to compute Down syndrome risks.[86A] This methodology allows a parameter set to be chosen and then the SDs and correlation coefficients modified according to the observed differences in variances between the laboratory and published estimates. Although there is some merit in this methodology, there are underlying assumptions and subtle requirements that can pose difficulties in implementation, even for the most sophisticated laboratory.

Verification of Calculated Down Syndrome Risks

Once a laboratory chooses a software package or implements an in-house algorithm for calculating Down syndrome risk, it should verify the accuracy of the calculated risks. One approach to verification for participants in the FBR/CAP Maternal Screening FP Survey (described earlier) is to use data contained in the multiple test evaluation report that accompanies the Participant Summary Report. The multiple test evaluation contains a laboratory-specific set of calculations that includes a verification of computed Down syndrome risk using the "parameter set" specified by each laboratory and their own reported maternal age and MoM values (triple or quadruple testing) for each serum specimen. The "computed risk" provided in the evaluation should compare closely with the laboratory's own reported risk. Unfortunately, many participating laboratories do not know the parameter set they use to generate Down syndrome risks or do not accurately report the parameter set used. Table A54-2 shows the reported parameter set and the most likely parameter set actually used for 228 laboratories in 2002. The latter was computed by applying various parameter sets to individual laboratory results until a "match" between the reported and computed risks was found. In some instances, the parameter set used was not identified. As an example, consider the first row in Table A54-2. A total of 96 laboratories reported using the parameters of Wald 88. Of these, our analysis confirms that 88 of these laboratories have indeed reported risks that are consistent with this parameter set. However, three of the laboratories actually appear to

TABLE A54-2 Comparison of Reported and Derived Parameter Sets for Computing Down Syndrome Risks Using AFP, uE_3, and CG Measurements (Triple Test)

Reported Parameter Set	Number of Laboratories	Derived Parameter Set			
		Wald 88	Knight 98	Wald 00	Unknown
Wald 1988 (12)	96	**88**	3	0	5
Knight 1998 (17, 18)	35	7	**27**	0	1
Wald 2000 (13-16)	43	21	2	**10**	10
Unknown/Blank	54	31	3	5	**15**
All	228	147	35	15	31

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

be using the Knight 98 parameters, and another five laboratories had risks that could not be matched with any of the parameter sets checked. Overall, 54 laboratories did not know the source of their parameter sets or did not answer the question (row labeled "Unknown/Blank"). The table also shows that the most common parameter set is the oldest, first published in 1988.[331] These laboratories should choose a newer, more appropriate parameter set.

When laboratories implement quadruple test testing, these 1988 parameters cannot be used, because they did not include DIA. Table A54-3 shows the parameter sets reported and computed for the laboratories offering quadruple test testing using the same analytic methodology as in Table A54-3. Although there are fewer data, there is still a significant discrepancy between the parameter set reported to be used to generate risks and the parameter set that actually appears to be the one used to generate risks. Laboratories have the responsibility of knowing which parameters are being used to calculate risks and whether they are appropriate for their population.

Another approach to verifying calculated risks is to use the tables located under the heading "Verification of Calculated Down Syndrome Risk" located on the CAP Therapeutic Drug/Endocrinology Resource Committee Web site (www.cap.org/apps/docs/committees/TDMEndo/verif_instr.html, accessed February 13, 2005). These tables provide risks for selected combinations of maternal age and MoM values for the parameter sets of Wald 88, Knight 98, and Wald 00. They also include risks for a parameter set designated Wald 1992, an interim set used before Wald 2000 that is still used by a few laboratories. The tables also provide risks based on the method of gestational dating (last menstrual period or ultrasound) and risks for both the triple and quadruple test for the more recent parameter sets. Instructions for using the tables are provided on the Web site.

Determining the Log Standard Deviation (SD) for Analyte A Using Microsoft Excel

The following steps can be used to reliably estimate the SD, on a logarithmic scale, for a specific analyte (e.g., AFP). This is done by a regression analysis on the linear portion of a probability plot (the x-axis is the value's z-score, and the y-axis is the log of the value). The process is begun by importing a set of MoM values (300 to 500 values) generated by the laboratory's screening program for the analyte in question into column A of an Excel spreadsheet. It is best to separate results based on last menstrual period dating from those with dates based on ultrasound measurements (US). For more information on using Excel, contact your computer services support personnel. The example below uses MoM data for AFP.

1. Importing and sorting the raw data: Select column A containing the AFP MoM values by clicking on the column heading **A.** Then choose **DATA,** then **SORT.** The default setting of **column A** and **ascending** should be already selected. Press **OK** and the data should be sorted from smallest to largest. Check to see if any "trash" is present (e.g., missing results, special codes, and > signs). Remove if found.
2. Computing necessary new data: In column B, row 1, enter the formula: = **COUNT(A:A).** This is the total number of observations in the dataset. In column C, row 1, enter = **(ROW(1:1) − 0.5)/B1.** This is essentially the cumulative probability (ranging from near 0 to near 1). In column D, row 1, enter the formula = **NORMSINV(C1).** This column now has the z-scores. In column E, row 1, enter the formula = **log(A1).** This computes the log of the AFP MoM. Copy the formulas from cells **C1, D1,** and **E1** through to the bottom of the spreadsheet.
3. Viewing the probability plot: Highlight columns D and E and click on the Chart Wizard (a button with colored bar charts on the toolbar). Select chart type XY Scatter to view the probability plot. The graph will generally be a relatively straight line, but most often deviations from the line will be observed in the extreme tails. If the data do not follow a straight line throughout, trimming is recommended. A commonly used trimming range is from the 5th to 95th percentiles, corresponding to z-scores (SDs) of −1.65 to +1.65. To plot only this range of values, select the data in columns D and E that are adjacent to column C entries ranging from about 0.05 (5%) to +0.95 (95%). Select XY Scatter on the Chart Wizard to view the trimmed scatter plot. If the plot is now essentially a straight line, go on to step 4. Figure A54-5 gives an example of a probability plot for AFP.

TABLE A54-3 Comparison of Reported and Derived Parameter Sets for Computing Down's Syndrome Risks Using AFP, uE_3, CG, and DIA Measurements (Quadruple Test)

Reported Parameter Set	Number of Laboratories	Derived Parameter Set			
		Wald 96	Knight 98	Wald 00	Unknown
Knight 1998 (17, 18)	25	3	**4**	0	11
Wald 2000 (13-16)	18	0	7	**7**	4
Unknown/Blank	3	1	0	1	**1**
All	46	4	11	8	16

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

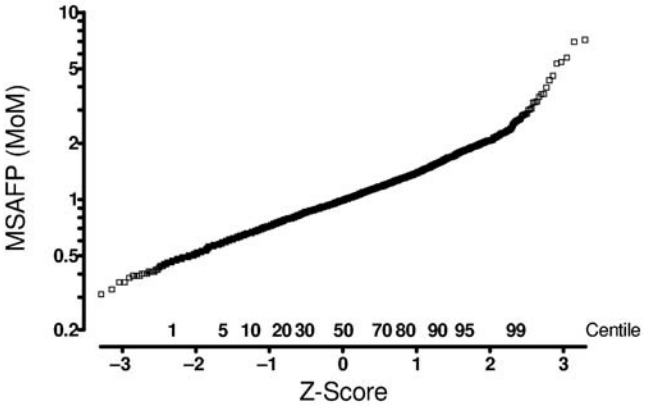

Figure A54-5 Probability plot for AFP measurements dated by ultrasound. X-axis (MoM values). Y-axis (z-score) with corresponding percentiles above the z-score.

4. Computing the SD: Click on cell **F1** and enter =. Then click on Functions (a button with $\mathbf{f_x}$ on the toolbar). A drop-down menu appears. Select **Statistical** in the left window and **Slope** in the right window of the drop-down menu. A formula box opens up. With the mouse, highlight the y-values (log MoM from column D). If trimming is necessary, select only the appropriate range of values. After the y-values are highlighted, click in the "**Known_x's** box." Highlight the corresponding x-values (z-scored) that are in column C using the same range as for the y-values. The log SD of analyte A appears in the cell you selected in column H.
5. Experimenting: Steps 3 and 4 can be repeated with different trimming values. As more data are removed from the tails, the log SD will become stable. It is this estimate that best summarizes data.

Determining the Correlation Between Analytes A and B

1. Importing and trimming the data: Import the MoM values for analytes A and B into columns A and B of a spreadsheet. For each analyte, determine the limit defining outliers (higher than +3, or lower than −3 SDs). Data beyond these limits will be excluded (trimmed) from the analysis. For example, suppose you determined that the log SD of AFP was 0.150. The lower limit for AFP is then 0 (the log mean) minus three times the log SD or −0.45. (This value is then antilogged to yield the lower trim limit of 0.35 MoM.) The upper limit is then +0.45 or 2.8 MoM. Therefore any AFP MoM values below 0.35 or above 2.8 should be excluded. When an outlier for one analyte is trimmed, the corresponding value of analyte B is also excluded because the data are paired. To apply the limits for analyte A, click on column headings A and B. Then choose **DATA,** then **SORT.** The default setting of **column A** and **ascending** should already be selected. Press **OK** and the data in column A will be sorted from lowest to highest. Delete all MoM values below 0.35 and above 2.8 in column A and the adjacent value in column B. Repeat the process for analyte B in column B.
2. Transform using logarithms: In column C, enter = **log(A1**) and in column D, enter = **log(B1).** Then copy those formulas down through the extent of data.
3. Creating a scatterplot of the transformed data: Select columns C and D. Click on the Chart Wizard and choose chart type **XY Scatter** to view the correlation plot. There should be no obvious outliers. If there are, go back to step 1 and delete them. Although the trimming method is efficient in identifying univariate outliers, bivariate outliers may need to be identified by sight and then removed one at a time. This is especially important if the correlation is relatively high.
4. Compute the correlation coefficient: Click on cell **E1.** Enter =, then click on the function key ($\mathbf{f_x}$ toolbar). Select **Statistical** in the left window and **CORREL** in the right window. A formula box opens. Highlight the y-values in column D (log of analyte A). Then click in box **Array 2.** Highlight the corresponding x-values in column C. Click OK. The correlation between the log of analytes A and B appears in the cell you selected.

CHORIONIC GONADOTROPIN BIOASSAY[66,68,114,286] AND AGGLUTINATION INHIBITION ASSAYS[313]

Bioassays, receptor assays, and agglutination inhibition assays are obsolete for detecting pregnancy. They are, however, of historical interest.

Bioassay and Receptor Assays

The underlying principle of CG bioassays is based on the luteotropic activity of CG. Thus injection of urine containing CG into experimental animals produces corpora lutea and corpora hemorrhagica in the ovaries of immature mice (Aschheim-Zondek test[286]), ovulation and corpora lutea formation in female rabbits (Friedman's test), and expulsion of spermatozoa in male frogs or toads (Galli-Mainini test). These cumbersome assays were among the first reliable pregnancy tests used. The in vivo bioassay systems were replaced by in vitro immunoassay tests, which are described later.[313] Some in vitro bioassays have been used, including radioreceptor[66] and cytochemical[68] assays. These CG tests are based on the ability of CG to stimulate steroid production by gonadal cell preparations after the interaction of CG with its cell membrane receptor (i.e., testosterone production by CG-stimulated Leydig cells).[114] The steroid produced in vitro is then measured by radioimmunoassay (RIA) and is related to the concentration of CG in the specimen. These methods have low limits of detection and permit measurements of the biological activity of circulating CG. They do not, however, distinguish between luteinizing hormone (LH) and CG; they are time consuming and expensive to perform; and their analytical performance depends on the preparation of the cells.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

Agglutination Inhibition Tests

Although now becoming obsolete, hemagglutination or latex particle agglutination inhibition tests were extensively used for qualitative detection of CG.[313] These tests could be divided into two categories: slide tests (e.g., Gravindex, Ortho Research Foundation) and tube tests (e.g., UCG-Test, Wampole Laboratories and Pregnosticon, Organon). The *slide test* was rapid, and results were obtained within 2 minutes. Antiserum to CG is added to the urine, followed by the addition of CG-coated latex particles. If there is no CG in the urine (nonpregnant patient), the antiserum reacts with the CG-coated latex particles and agglutination occurs (negative test). However, during pregnancy, the presence of CG at more than approximately 1500 IU/L in the urine neutralizes the CG antibodies, and no agglutination occurs within 2 minutes (positive result). The *tube test* is also based on inhibiting agglutination, but CG-coated erythrocytes are used instead of latex particles. This test requires a 2-hour incubation step and is positive at CG concentrations as low as 150 IU/L. Both agglutination inhibition techniques have been replaced by more sensitive immunoradiometric (IRMA) or immunoenzymetric (IEMA) techniques.

DETERMINATION OF ΔA_{450} IN AMNIOTIC FLUID[201]

The concentration of bilirubin is generally too low (~0.01 to 0.03 mg/dL; 0.17 to 0.51 μmol/L) to be measured by standard photometric techniques, but the determination can be done rapidly, accurately, and directly by absorption spectrophotometry. The maximum absorbance of bilirubin is at 450 nm. In the absence of significant amounts of bilirubin, the absorbance spectrum for the amniotic fluid between 365 and 550 nm is nearly exponential (see Figure 54-16 in Chapter 54 of the 4th edition of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*). When plotted on a semilog scale, the degree to which the curve deviates from a straight line at 450 nm is linearly proportional to the concentration of bilirubin in the amniotic fluid. This is the change in absorbance at 450 nm (ΔA_{450}), which is still occasionally referred to as ΔOD_{450} in the clinical literature. There is normally a small amount of bilirubin in amniotic fluid, and this amount changes with gestational age (see Figure 54-17 in Chapter 54 of the 4th edition of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*). To properly interpret the $\Delta A_{450,}$ it is necessary to know the gestational age.

Specimen

The amniotic fluid specimen is obtained by amniocentesis with a 22-gauge needle under ultrasound guidance, taking care not to contaminate the specimen with blood. A total of 10 mL should be withdrawn. Because bilirubin is unstable in light, the specimen should be protected from light during transport to the laboratory and during storage. Most amniocentesis trays contain a brown plastic tube with a screwtop. If a clear tube must be used, wrap the specimen in aluminum foil. Liley[201] found that the absorbance peak had a half-life of 10 hours in a lighted laboratory and 12 to 18 minutes in winter sunlight. When stored in the dark, however, the peak is stable for 30 days at room temperature and for at least 9 months under refrigeration.

Instrument

A computer-controlled spectrophotometer is most conveniently used, and the fluid is scanned between 340 and 560 nm. Ideally the instrument would record the absorbance on a semilog scale against wavelength on a linear scale, but modern instruments do not have this feature. Burnett has shown that using other methods for determining the baseline can lead to significant error (see Burnett RW. Instrumental and procedural sources of error in determination of bile pigments in amniotic fluid. Clin Chem 1972;18:150-4). If a manual spectrophotometer is used, individual absorbance readings should be taken about every 10 nm and recorded for graphing on a semilog plot. Because the major contaminant of concern is oxyhemoglobin, with an absorbance peak at 410 nm, it is important that the instrument have a narrow bandpass to minimize interference by this compound when making the A_{450} reading.

Procedure

1. Clear the specimen of particulate matter by centrifugation at 2000 × *g* for 5 minutes.
2. Fill a cuvet with undiluted amniotic fluid.
3. Zero the spectrophotometer using a sodium chloride solution, 0.15 mol/L.
4. Scan the fluid from 340 to 560 nm, recording wavelength versus log (absorbance). If a manual spectrophotometer is used, make individual absorbance readings at the following wavelengths: 350, 365, 380, 390, 400, 410, 415, 420, 430, 440, 450, 460, 470, 485, 500, 515, 530, 540, and 555. Plot log (absorbance) against wavelength.
5. On the absorbance plot, draw a straight line (the baseline) from the linear area of the curve at 350 to 375 nm to the linear area of the curve at 525 to 550 nm.
6. Construct a line perpendicular to the x-axis from the absorbance peak at 450 nm to the baseline. The difference between the peak and baseline represents the ΔA_{450} (see Figure 54-16 in Chapter 54 of the 4th edition of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*).
7. If there is an oxyhemoglobin peak at 410 nm, determine the ΔA_{410} in a similar fashion.

Calculations

In the absence of other pigment peaks, the ΔA_{450} derived from the graphic method described earlier should be reported directly to the nearest 0.001. If oxyhemoglobin is present as a peak at 410 nm, then 5% of the ΔA_{410} should be subtracted from the ΔA_{450} and that number reported as the

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

ΔA_{450}. There are other mathematical correction methods in the literature and a chloroform extraction technique.[127]

SURFACTANT/ALBUMIN RATIO BY FLUORESCENCE POLARIZATION (TDX FLM II)[26,125,309]

The technique of fluorescence polarization is the most commonly used quantitative method as judged by enrollment in the College of American Pathologists Fetal Lung Maturity proficiency test survey (see Table 54-6 in Chapter 54 of the 4th edition of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*). This rapid test has better precision than the lecithin/sphingomyelin (L/S) ratio.[295] The test was originally described in 1976 by Shinitzky and colleagues, who used diphenylhexatriene (DPH) as the fluorescent dye. Although the DPH test is predictive of fetal lung maturity, many laboratories had difficulty working with this dye. It is an easily oxidized compound that absorbs ultraviolet (UV) light. The UV fluorescence polarimeter instrument, the FELMA, was difficult to maintain. These disadvantages prevented widespread use of DPH fluorescence polarization in clinical laboratories. Tait and associates[309] improved the technique by using a more stable fluorescent dye, NBD-PC, and a commercial polarimeter, the Abbott TDx. Russell[278] developed a commercial version of the assay using a slightly different dye, PC-16. The results of the two assays have a strong nonlinear, inverse correlation.[21,24]

The commercial version is calibrated with solutions containing differing phospholipid to albumin ratios, expressed as milligrams of surfactant per gram albumin. The vast most laboratories performing fluorescence polarization testing for fetal lung maturity use the commercial version of the assay. The NBD-PC method is available on the Evolve Web site for those laboratories that are willing to prepare the reagents and perform the calculations required for interpretation.

Fluorescence polarization is a dimensionless ratio with values from 0.000 to 0.500 for dilute solutions containing fluorescing compounds (see Chapter 3).[193] Polarization (P) measures the rotational diffusion of the fluorophore relative to its fluorescent half-life. If the half-life is short compared with the rate of rotational diffusion, P will be high. In contrast, if molecular rotation is faster than the excited state decay, then P will be low. Shinitzky proposed that for amniotic fluid lower polarization values reflected a decrease in the microviscosity of surfactant phospholipids. The fluidity of these phospholipids paralleled the change in lipid composition with maturation of the fetal lungs.[295] This mechanism is incorrect for the NBD-PC method. NBD-PC binds to albumin and to surfactant; thus the resulting polarization is a function of the surfactant/albumin ratio.[22]

Materials, Reagents, and Instruments

1. TDx buffer (Abbott Laboratories), consisting of 0.1 mol of sodium phosphate, 1 g of sodium azide, and 0.1 g of bovine γ-globulin per liter. The pH is 7.4 at room temperature.
2. Fluorescent dye C6-NBD-PC (Avanti Polar Lipids, Pelham, AL, catalog No. 810130), 75 µg/mL in TDx buffer adjusted to pH 5. Dry the contents of a 2-mg vial of NBD-PC in an Erlenmeyer flask under vacuum, leaving an orange film. Add 26.7 mL TDx buffer that has been previously adjusted to pH 5.0 with hydrochloric acid; mix gently. The solution should be clear and yellow, with an absorbance of 1.5 at 480 nm. Add more buffer if the absorbance is >1.5. Store in aliquots at −20 °C; store aliquot for current use at 4 °C.
3. 1% (vol/vol) Triton-X 100 in TDx buffer, pH 7.4. Store at room temperature.
4. TDx Analyzer (Abbott Laboratories, Irving, Tex.), standard production model calibrated to 33.5 °C to 34.5 °C according to the manufacturer's instructions.

Procedure

1. Mix the specimen tube by inverting it 5 to 10 times or place on a tube rocker for at least 2 minutes. Transfer the entire contents to a clean, clear test tube. Note the condition of the amniotic fluid (i.e., xanthochromic, meconium stained, or bloody). Centrifuge the fluid at $400 \times g$ for 2 minutes at 4 °C to remove particulate debris. Decant all the fluid into a new tube and place on a tube rocker.
2. Place cuvets in TDx carousel positions 1 to 10, one for each Triton-X 100, control, and specimen as necessary.
3. Deliver 0.5 mL of sample into each cuvet.
4. Add 1 mL TDx buffer to each sample. Break any large bubbles at the meniscus with a wood applicator stick. Avoid carryover.
5. Place the carousel into the TDx and close door. Read background fluorescence and polarization using Photo Check (press TEST 2.2 and RUN). The TDx measures the fluorescence intensity, I, and the fluorescence polarization, P. The dimensionless polarization is reported ×1000 in artificial units of mP; thus it ranges from 0 to 500 mP.
6. While the background reading is in progress, place a 0.5-mL Combi-tip on an Eppendorf repeater pipette and draw up sufficient NBD-PC solution to add 10 µL to each cuvet.
7. Remove the carousel. Start a stopwatch and immediately add 10 µL NBD-PC solution to the first cuvet and to each of the remaining cuvets at 3-second intervals.
8. Mix the solution in each cuvet by drawing up 1 mL in a pipette and redispensing. Avoid carryover. Break any large bubbles on the meniscus.
9. Return the carousel to the TDx for total fluorescence and polarization readings. When the stopwatch reaches 2 minutes 30 seconds, run Photo Check (as in step 5).
10. At 5 minutes 30 seconds, begin listening for the TDx reading sequence. The TDx changes from constant rotation of half to full revolutions (incubating), to

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

indexing a position every 3 seconds (reading). When reading begins, stop the stopwatch and record the time. Acceptable times are from 6 to 7 minutes.
11. Remove the carousel and measure the temperature of the solution in two cuvets with a thermistor. Acceptable temperatures are from 33.5 °C to 34.5 °C.

Calculations

1. Calculate the net fluorescence intensity for each cuvet,

$$I_{net} = I_{total} - I_{background}$$

2. Convert all TDx polarization results to true P units by multiplying by 1000.
3. Convert all background and total polarization to anisotropy,

$$r = \frac{2P}{3 - P}$$

4. Calculate net anisotropy for each cuvet,

$$r_{net} = \frac{r_{total} I_{total} - r_{background} I_{background}}{I_{net}}$$

5. Convert net anisotropy to polarization,

$$P = \frac{3r}{2 + r}$$

6. Multiply polarization by 1000 to report in the artificial units mP.

Comments

1. An NBD-PC fluorescence polarization value of <260 mP is considered to reflect mature lungs, values between 260 and 290 mP are considered transitional, and values >290 are considered to reflect immaturity.[69,308] Using 260 mP as the cutoff, this test has a clinical sensitivity of 94% and a clinical specificity of 84%. The supplemental use of the L/S ratio for those patients with transitional results is of little benefit. The 260 mP cutoff is appropriate for high-risk pregnancies. In the setting of a patient who needs a cesarean section at term, when there is no penalty for delaying delivery, a cutoff of 230 mP is more appropriate.
2. If there is <0.5% blood in the amniotic fluid, the results are not affected. Contamination with more than this amount tends to increase low results and decrease high results.[309] Clearly mature (<230 mP) and immature (>290 mP) results can be relied on for predicting fetal lung status. Results between these values cannot be interpreted.
3. Because of improved pregnancy management, very few infants with respiratory distress syndrome (RDS) are born to women with diabetes. Thus exact estimates of clinical sensitivity and specificity are not available in this clinical setting. The predictive value of a mature status in a patient with diabetes mellitus appears to be equivalent to that in a patient without diabetes.[69] A multicenter trial concluded that diabetes mellitus did not affect the medical decision limit of fluorescence polarization (using the commercial version of the assay).[203]

LAMELLAR BODY COUNTS[25]

Lamellar body particles can be measured directly using the platelet channel of a standard hematology cell counter. Many of these surfactant particles are from 2 to 20 fL in volume, an interval that is commonly used to enumerate and size platelets in whole blood specimens. Several investigators have proposed that lamellar body counting be used as a rapid fetal lung maturity test.[25,112] This new method has been shown to be cost effective (see Lewis PS, Lauria MR, Dzieczkowski JS. Amniotic fluid lamellar body count as a cost effective screening test for fetal lung maturity. Am J Obstet Gynecol 1997;176:S44) and reliable in clinical outcome studies.[25,45,99,118,255] Because of different platelet identification algorithms, counts will be lower or higher on some instruments.[305]

Materials and Instruments

1. Coulter Counter Model S-PLUS STKR (Coulter Electronics, Hialeah, Fla.). Other Coulter Counter model hematology cell counters perform well.
2. Isoton III (Coulter Diagnostics, Hialeah, Fla.) is a balanced electrolyte solution used to dilute blood samples analyzed on the Coulter Counter.

Procedure

1. Invert the amniocentesis tube 20 times and transfer the entire contents to a clear test tube. Reject specimens contaminated with meconium, those with more than 1% blood, or those containing readily apparent mucus.
2. Centrifuge for 2 minutes at 400 × *g*. Decant the entire contents into a new test tube and place it on a tube rocker for 2 minutes. This step is optional, but the decision threshold must be raised 8% when using uncentrifuged specimens.
3. Wipe clean the aspiration tip of the cell counter with a gauze pad and 50% bleach, then aspirate Isoton at least twice into the instrument.
4. Aspirate amniotic fluid into the instrument. The lamellar body count per microliter is determined by the platelet channel.
5. Print a cell histogram with each analysis.

Comments

1. Priming the Coulter Counter with Isoton purges any blood remaining in the tip from previous analyses.
2. The Coulter Counter Model S-PLUS STKR requires a minimum of 125 µL. Typical day-to-day precision (SD) is 3500 counts/µL (5%) at an average count of 70,500/µL and 7800 counts/µL (4%) at an average count of 209,400/µL.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

3. Centrifugation slows the procedure, reduces the counts by 8%, and does not improve the precision of the assay. Use of uncentrifuged specimens is recommended. Maturity is indicated by having a lamellar body count of at least 55,000/μL in a centrifuged specimen or 60,000/μL in an uncentrifuged specimen. Other studies recommend lower decision limits. In a 3-year prospective study, Ashwood et al found that all 28 cases of RDS were correctly classified using these thresholds. Fifty-five percent of infants not developing RDS had results greater than the cutoff.[25]
4. More than 1% vol/vol blood can decrease lamellar body count by up to 20%.[23] Vaginal pool fluids containing obvious mucus can have very high erroneous counts. These contaminated fluids should not be tested using this method. Moderate meconium contamination does not interfere.[25]

DETERMINATION OF LECITHIN/SPHINGOMYELIN RATIO AND SATURATED PHOSPHATIDYLCHOLINE[315]

The procedures described here should not be considered definitive or representative. Quantitative assay of DSPC requires removal of unsaturated lecithin from the sample. Osmium is a very powerful oxidizing agent that reacts with double bonds in fatty acids and renders lecithins containing unsaturated fatty acids insoluble.

Specimen

A minimum of 3 mL of amniotic fluid should be obtained, preferably by transabdominal amniocentesis. Specimens obtained from a pool of fluid in the vagina immediately after rupture of the membranes are acceptable, unlike those collected for the shake test, although the L/S ratio can be affected.

Materials and Reagents

1. Chromatogram sheets, Eastman 6061 Silica Gel without fluorescent indicator, catalog No. 13179 (Eastman Chemical Co., Kingsport, Tenn.). Sheets must be activated before use by heating for 24 hours in a 100 °C oven.
2. Developing solvent. 65 parts chloroform, 25 parts methanol, 4 parts deionized and distilled water, vol/vol/vol.
3. Bromothymol blue dye solution. Add 64 mL of sodium hydroxide solution (1 mol/L) to 896 mL deionized water. Dissolve in this solution 10 g of boric acid powder. Then add 500 mg of bromothymol blue dye and stir with a magnetic bar until dissolved.
4. Osmium tetroxide, 7 g/L.
   Stock solution: 1 g OsO_4 + 10 mL CCl_4
   Working solution: 0.7 mL stock + 9.3 mL CCl_4
5. DSPC calibrator, 100 ng/μL. Mix 9 mL of chloroform plus 1 mL of methanol as the solvent and add 1 mg of dipalmitoylphosphatidylcholine. Store the solution in the refrigerator.
6. L/S control. Dissolve 30 mg each of lecithin and sphingomyelin in 10 mL of chloroform. Store this solution in the refrigerator.

Procedure

Lipids are extracted from the amniotic fluid. Then separate protocols are used for L/S ratio and DSPC determinations.

Preparation of the Amniotic Fluid Specimen

1. Centrifuge the fluid as described earlier under Specimen Handling.
2. Pipette 3 mL of the well-mixed supernatant into a 50-mL glass tube.
3. Add 3 mL of methanol and vortex well.
4. Add 6 mL of chloroform and vortex for 30 seconds.
5. Centrifuge at 500 × *g* for 5 minutes.
6. Aspirate off the lower (chloroform) phase and transfer into a 15-mL tube and evaporate to dryness under flowing N_2 in a 60 °C water bath.
7. Rinse down the sides of the tube with a small amount of chloroform and evaporate again as described earlier.
8. Redissolve the residue in 150 μL of chloroform.
9. Transfer 50 μL to a 12 × 75-mm tube and evaporate tubes containing 100 and 50 μL of chloroform; extract to dryness. Chill on ice.

Determination of the L/S Ratio

10. Add two to three drops of 4 °C acetone to the residue in the 15-mL tube containing 100 μL of amniotic fluid residue and agitate to dissolve.
11. Add 0.75 mL of cold acetone and let stand on ice for 5 minutes.
12. Centrifuge at 800 × *g* for 1 minute. Decant and discard acetone.
13. Dry the tube under flowing N_2 and chill.
14. Redissolve the residue in 100 μL of chloroform and spot onto activated chromatogram sheets in two 2-μL, two 5-μL, two 10-μL, and two 20-μL bands. Spot a 10-μL and a 20-μL band of the control for reference. Leave blank lanes between the samples so that the sheets can be read in the reflectance densitometer.
15. Dry the sheet in an oven for 2 minutes.
16. Develop in a tank with 1 cm of solvent and allow the front to migrate to within 1 cm of the top of the sheet.
17. Dry in an oven for 2 minutes and stain by immersion in a tank with bromothymol blue dye. Do not spray.
18. Blot off the excess dye and dry in an oven for 5 minutes.
19. Cool to room temperature and read in a reflectance densitometer.

Determination of DSPC

20. Place the 12 × 75-mm tube containing the 50-μL amniotic fluid residue prepared earlier in step 9 in a rack under a hood.
21. Add 0.5 mL of the OsO_4 working solution and allow the solution to stand at room temperature for 15 minutes.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

22. Evaporate under N_2 in the hood and redissolve the residue in 50 µL of chloroform.
23. Place three 10-µL spots onto the thin-layer chromatography (TLC) sheet, leaving blank lanes between samples.
24. Warm the DSPC calibrator solution to room temperature and place two 10-µL spots (1 µg) onto the TLC sheet.
25. Dry the sheet in an oven. If spots are particularly dark (usually cases of heavy blood contamination), leave in the oven for 10 to 15 minutes.
26. Develop, stain, and read chromatograms as earlier in steps 16 to 19 for the L/S procedure.

CALCULATION

$$\text{DSPC in specimen}\,(\mu g/dL) = (A_{\text{specimen}} \times 1.0 \times 100)/(A_{\text{calibrator}} \times 0.2) = (A_{\text{specimen}}/A_{\text{calibrator}}) \times 500$$

where
1.0 = amount of calibrator used, in micrograms.
100 = converts to deciliters.
0.2 = amount of original amniotic fluid, in milliliters.

Example. If sample spots give absorbance readings of 33, 35, and 37 (average, 35) and the calibrator spots read 20 and 22 (average, 21), then

$$\text{DSPC}\,(\mu g/dL) = 35/21 \times 500 = 833$$

INTERPRETATION

Using this method, the L/S ratio indicates mature lungs if it exceeds 2.0, and the DSPC implies maturity if it exceeds 500 µg/dL. Both of these tests predict fetal lung maturity more reliably than they predict immaturity. About 2% to 3% of babies delivered within 24 hours of obtaining an L/S ratio of >2.0 can be expected to develop RDS; thus 97% to 98% of babies predicted to be mature will in fact be mature. Almost half of the infants with L/S ratios between 1.5 and 2.0, however, will not develop RDS. Thus in contrast to the high degree of reliability of a prediction of maturity, only half of the babies predicted to be immature will in fact be immature. Corresponding numbers for DSPC are similar. Using an OsO_4 and TLC technique, Tsai and colleagues[319] reported that 550 µg/dL should be used as the decision level for DSPC. In a follow-up study, they concluded that the DSPC concentration is more reliable than the L/S ratio when the results show immaturity; both are equivalent when the results suggest maturity.[320]

COMMENTS

1. It is important in the initial extraction procedure first to create a monophasic system with the addition of methanol and then to add the chloroform to form the biphasic system. Insoluble proteins are left at the interface. Failure to mix thoroughly with methanol first leads to an inadequate extraction and loss of lipid in the protein layer.
2. Although ammonium sulfate charring of lecithin and sphingomyelin spots has been popular, sphingomyelin chars more intensely than an equal weight of dipalmitoyl lecithin.[53] Furthermore, charring is less intense as the degree of saturation of the lipid being examined increases.[301] Staining with bromothymol blue has been shown to be a saturation-insensitive technique. Lecithin that is highly saturated stains with the same intensity as relatively unsaturated lecithins.[301] The major disadvantage of bromothymol blue staining is that it fades rather rapidly; thus chromatograms should be scanned promptly after staining. Dipping the TLC sheet is preferable to spraying because dipping gives more uniform color development.
3. The major disadvantage of this one-dimensional technique is that it fails to separate phosphatidylinositol (PI) from lecithin. It thus may slightly overestimate the L/S ratio.
4. Acetic acid may be added to the developing solvent to improve the separation of the PI and phosphatidylserine (PS) from the lecithin. However, this interferes with color development with bromothymol blue staining.
5. Serum has a large concentration of lecithin and sphingomyelin. The ratio varies between 1.5 and 2.0, depending on the individual. The values of blood-contaminated specimens therefore tend to be drawn into that interval from either higher or lower values. A high L/S ratio in the presence of even substantial blood contamination can safely be interpreted as reflecting mature lungs.[135] Similarly, contaminated samples with very low ratios clearly reflect immature lungs. Borderline values of bloody specimens cannot be interpreted, because they may represent either very immature values falsely elevated or mature values falsely depressed. Various effects of meconium contamination have been reported, including some evidence that the L/S ratio may be changed before the degree of contamination is visible to the eye.[171] The chromatograms of fluids heavily contaminated with meconium are not interpretable.
6. There is no DSPC in either blood or meconium. Experimental contamination of amniotic fluid samples with either of these does not change the DSPC value.[315]
7. Vaginal contamination of specimens obtained from a pool of fluid that has been present in the vagina for a relatively brief period does not affect either test.[109,258]
8. L/S ratio methods are not very precise. For example, a proficiency testing survey by the CAP reported the following results (proficiency test sample number, mean, SD, and coefficient of variation [CV]): LM-09, 4.46, 1.18, 26%; and LM-10, 2.31, 0.62, 27%.[79]

DETERMINATION OF THE LUNG PROFILE[191,192]

This method for assessing fetal lung maturity was invented by Marie Kulovich and Louis Gluck in the early 1970s. Although it is still offered by some reference laboratories, most hospital laboratories have substituted newer techniques.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

Principle

The lung profile, also referred to as the two-dimensional lung profile, provides the simultaneous determination of the L/S ratio, phosphatidylglycerol (PG), and PI as percentages of total phospholipid, and the saturated lecithin as a percentage of total lecithin. By using the two-dimensional system, this technique separates the acidic phospholipids PG and PI from the lecithin fraction so that the lecithin is not overestimated. This procedure depends on cold acetone precipitation to separate the highly saturated lecithins from the less saturated lecithins. Some researchers have reported findings that may indicate that unsaturated lecithins are less important for lung maturity.

Specimen

Amniotic fluid (5 mL or more) should be obtained by amniocentesis or from a free flow of fluid in the vagina after rupture of the membranes. Specimen handling conditions should be as noted earlier.

Materials and Reagents

1. TLC plates, silica gel H with 5% ammonium sulfate, 20 × 20 cm. Activate before use by storing in a 110 °C oven for 24 hours.
2. Developing solvents.
   a. System one: 65 parts chloroform, 25 parts methanol, 4 parts deionized and/or distilled water, 8 parts glacial acetic acid, vol/vol/vol/vol.
   b. System two: 40 parts tetrahydrofuran, 28.5 parts methylal, 7.8 parts methanol, 4.2 parts ammonium hydroxide (2 mol/L), vol/vol/vol/vol.
3. PG standard, 10 µg/µL. Dissolve 10 mg of PG in 1 mL of solvent (9 parts chloroform, 1 part methanol).
4. L/S standard. Dissolve 30 mg each of lecithin and sphingomyelin in 10 mL of chloroform.

Procedure

1. Centrifuge at least 5 mL of amniotic fluid as described earlier under Specimen Handling.
2. Extract the supernatant by adding an equal volume of methanol. Vortex well.
3. Add chloroform (twice the volume of the original sample) and again vortex for 30 seconds.
4. Centrifuge at 500 × *g* for 5 minutes.
5. Aspirate off the lower, chloroform phase into a 15-mL conical centrifuge tube and evaporate to dryness under flowing N_2 in a 60 °C water bath.
6. Concentrate the specimen to the tip of the tube by rinsing down the sides with several drops of chloroform and evaporate.
7. Place the tube in an ice bath and add two drops of cold acetone with a Pasteur pipette. Agitate slightly. A white precipitate should form.
8. Add 0.75 mL of cold acetone and allow to sit in an ice bath for 15 minutes.
9. Centrifuge at 3000 × *g* for 2 minutes.
10. Transfer the supernatant to a 15-mL conical centrifuge tube. Dry the precipitate under flowing N_2 at 60 °C.
11. Evaporate the supernatant to dryness under flowing N_2 in a 60 °C water bath. Concentrate the specimen down to the tip of the tube by rinsing down the sides with several drops of chloroform and evaporate.
12. Dissolve the acetone-precipitable fraction (from step 10) in 30 µL of chloroform. Place 12 µL of this solution onto the activated TLC plate at the bottom right-hand corner, 3 cm from the right-hand edge. Dry the spot.
13. Dissolve the acetone-soluble fraction (from step 11) in 30 µL of chloroform. Place 12 µL onto the activated TLC plate at the bottom far left-hand corner. Dry the spot.
14. Place 10 µL of the L/S standard and 2 µL of the PG standard in the left-hand corner in separate lanes. Dry the spots.
15. Develop in the first solvent system until the front has run 10 cm from the origin. Dry the plate at approximately 70 °C for 7 minutes. Cool to room temperature.
16. Turn the plate 90° so that the original right side is now down. Spot L/S (10 µL) and PG (2 µL) standards on the right-hand corner, 3 cm from the bottom of the plate. Dry the spots.
17. Develop in the second solvent system until the front has run 10 cm from the origin. (Thus the acetone-soluble fraction will have been run in one dimension only, and the sample and the L/S and PG standards will have been run in both dimensions.)
18. After drying the plate for 10 minutes at room temperature, place it on a hot plate preheated to 280 °C until thoroughly charred (15 minutes).
19. All spot areas are then measured in a reflectance densitometer.

Calculations

The ratio of the areas under the curves for the saturated lecithin and sphingomyelin is calculated and reported as the L/S ratio to the nearest 0.1.

The areas under the curves for the saturated lecithin and unsaturated lecithin are added. The area for the saturated lecithin is then expressed as a percentage of this total.

The areas under the curves for the total acetone-precipitable fraction (which includes PG, PI, PS, phosphatidylethanolamine [PE], saturated lecithin, and sphingomyelin) are then summed. The areas of the PG and PI spots are then expressed as percentages of this total.

Comments

1. The individual values for each of the determinations within the lung profile are considered when a judgment about fetal pulmonary maturity is made. The L/S ratio indicates fetal lung maturity if it is 2.0 or greater. A PG level in excess of 3% of the total acetone-precipitable fraction indicates fetal lung maturity. Although there is a trend for the percentage of saturated lecithin that is acetone precipitable to rise with increasing L/S ratio and

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

PG percentage, there is no critical level cited earlier at which the fetal lungs would be presumed to be mature. The level of PI in amniotic fluid expressed either as a percentage or total acetone-precipitable phospholipid[192] increases from 16 weeks of gestation to a peak at 36 weeks and then decreases toward term. Thus a low or intermediate value for PI could represent a point on the curve at 30 to 34 weeks with immature lungs on the way up or a point at 38 to 42 weeks with mature lungs on the way down.

2. The two-dimensional technique separates the acidic phospholipids PG and PI from the lecithin, thus providing a lower and more conservative estimate of the L/S ratio than the one-dimensional technique discussed earlier. For patients whose pregnancies are uncomplicated by diabetes or isoimmune disease, the rate of false predictions of maturity is 2%.[192] The same criticism of the relatively high (30%) incidence of false predictions of immaturity (L/S ratio <2.0 though no RDS develops) pertains to this L/S ratio technique as well.
3. The exact role of PG in lung surfactant is unclear.[55] It has been said that the appearance of PG in the amniotic fluid indicates the final biochemical maturation of surfactant.[156,191] It is clear, however, that PG can be found in measurable quantities in amniotic fluid as early as 32 weeks,[129] and that its presence in small quantities does not necessarily imply that the fetal lungs are mature.[95,129,221] The concentration of PG in amniotic fluid rises with gestational age, very closely reflecting the L/S ratio. Most qualitative techniques are positive when PG exceeds about 2.0 μmol/L. Using this level, mature results almost always are correct, but immature results are frequently wrong. When sensitive techniques are used, cutoff values for PG can be established above which no RDS is noted,[221] but the problem of a high percentage of falsely immature results remains. Thus the difference between amniotic fluid specimens reflecting mature lungs and immature lungs is a quantitative difference in PG concentration and not a qualitative difference in its presence or absence. Given these facts, it is not clear that waiting for PG to appear in the amniotic fluid before declaring the lungs to be mature offers any advantage over simply selecting a higher value for the L/S ratio. This is also true for pregnancies complicated by maternal diabetes mellitus.[96]

   Determination of PG has clinical utility in cases of blood or meconium contamination of the amniotic fluid. Like DSPC, PG is not found in either blood or meconium, and therefore results are not affected by the presence of either of these contaminants. Very large amounts of blood or meconium can obscure the presence of PG. A qualitative rapid agglutination test for PG, UltraSensitive AmnioStat-FLM, is available from Irvine Scientific (Santa Ana, Calif).[115,134,281] Several enzymatic-based tests for PG have also been published.[18,131,174,227]
4. Many investigators believe that the acetone precipitation step is critical to the procedure, because it precipitates the highly saturated lecithins thought to be responsible for the majority of the surface activity of surfactant. However, cold acetone does not precipitate saturated lecithin specifically or quantitatively (see Touchstone JC, Levin SS, Dobbins MF, Beers PC. Analysis of saturated and unsaturated phospholipids in biological fluids. J Liquid Chromatogr 1983;6:179-92). The solubility of lecithin in cold acetone is dependent on a large number of factors that are difficult to control, including the exact time and temperature conditions, the water and chloroform content of the acetone, the lipid composition of the original amniotic fluid sample, and the preliminary centrifugation conditions.[53] Precipitation of DSPC is not quantitative and may vary from 60% to 90% among samples (see Penney LL, Hagerman DD, Sei CA. Specificity and reproducibility of acetone precipitation in identifying surface-active phosphatidylcholine in amniotic fluid. Clin Chem 1976;22:681-2). Composition studies have shown that the acetone precipitate may contain both saturated and unsaturated lecithins.[315] One study found a difference in the numerical values of L/S ratios determined with and without acetone precipitation, but did not find a difference in the ability of the two techniques to predict clinical outcome (see Hobson DW, Spillman T, Cotton DB. Effect of acetone precipitation on the clinical prediction of respiratory distress syndrome when utilizing amniotic fluid lecithin/sphingomyelin ratios. Am J Obstet Gynecol 1986;154:1023-6). Another study showed that total extractable lipid, the saturated fraction, and the unsaturated fraction all lowered surface tension in a similar fashion (see Ruiz Budria J, Abbad Bara JM, Fabre Gonzalez E, et al. Phospholipid surface tension: the diagnostic utility of amniotic fluid and its lipid extract, an analysis of the value of precipitation with cold acetone. Clin Chem 1989;35:800-3). Brown and Duck-Chong[53] have concluded that there is no advantage to including the acetone precipitation step in the L/S ratio procedure because it adds variability and procedure time.
5. Comments made with respect to the importance of centrifugation of the original amniotic fluid specimen, initial extraction of the fluid with methanol and chloroform, and the charring procedure of the TLC in the one-dimensional technique are pertinent to the lung profile as well.

FOAM STABILITY INDEX[292]

Many laboratories used a commercial version of this test, called Lumadex, FSI Fetal Lung Maturity Test (Beckman Instruments, Fullerton, Calif.), which was introduced in 1982.[205,291] Beckman Instruments discontinued this test in 1997. Laboratories may want to use the procedure described here as an alternative.

PRINCIPLE

When pulmonary surfactant is present in amniotic fluid in sufficient concentration, the fluid is able to form a highly

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

stable surface film that can support the structure bubbles. Other substances in the fluid, including proteins, bile salts, and salts of free fatty acids, are also capable of forming a stable foam, but these can be excluded from the film by ethanol, which competes with these other substrates for a position in the surface film. Clements and colleagues[71] first described this test. Refer to the first edition of this textbook for the detailed procedure. Sher and Statland and others[291-294] devised a test with six possible outcomes that they term the foam stability index (FSI). This test makes use of the principle that more surfactant activity is necessary to support a stable foam as the fraction of ethanol in the mixture is increased. Thus a fixed volume of undiluted amniotic fluid is mixed with increasing volumes of ethanol, and the largest fraction of ethanol in which the amniotic fluid is still capable of supporting a foam is determined. The highest fraction of ethanol at which a positive reading is obtained is the FSI.

Materials and Reagents

1. 95% ethanol. Add 5 mL deionized water to 95 mL absolute ethanol. Store in a tightly sealed container.

Procedure

1. Centrifuge the amniotic fluid at 1000 × *g* for 3 minutes. Decant the supernatant.
2. Gently mix the supernatant without creating foam by inverting several times.
3. Set up six 12 × 75 mm screw-up plastic tubes and label them 0.50, 0.48, 0.47, 0.46, 0.45, and 0.44.
4. Carefully pipette the following volumes of 95% ethanol into the respective tubes: 0.55, 0.51, 0.49, 0.47, 0.45, and 0.43 mL.
5. Add exactly 0.50 mL of the amniotic fluid supernatant to each tube.
6. Cap the tubes and shake them vigorously for 30 seconds. Allow the contents to settle for 15 seconds and then examine.
7. Under bright overhead light against a flat black background, examine for the presence of bubbles at the edge of the air-fluid meniscus. A ring of bubbles 360° around the tube signifies a positive result. Record the highest concentration of ethanol at which a positive reading is obtained. This is the FSI.

Comments

1. A value of 0.47 or greater should be interpreted as mature. In two series, a combined total of 270 fetuses with an FSI of 0.47 or greater was reported, 2 of which developed RDS. In 110 fetuses with an FSI of 0.46 or less, 44 (40%) developed RDS. Thus this test is associated with more false predictions of immaturity than the L/S ratio.
2. Tubes and stoppers must be clean and free of detergents to prevent false-positive readings.
3. The final concentration of the ethanol is critical. A 95% solution of ethanol is hygroscopic; therefore careful attention must be paid to the preparation and storage of the ethanol reagent. The 95% ethanol must be accurately pipetted into the amniotic fluid.
4. The test should be conducted at 20 °C to 25 °C. Temperatures substantially below this may retain a relatively unstable foam, whereas higher temperatures may cause deterioration of an otherwise stable foam.[181]
5. Specimens contaminated with either blood or meconium tend to give a falsely mature result. Because a significant percentage of fluid samples submitted to a clinical laboratory may be contaminated, this is an important limitation of this test.

APPENDIX 55

Inborn Errors of Amino Acid, Organic Acid, and Fatty Acid Metabolism

Piero Rinaldo, M.D., Ph.D., Sihoun Hahn, M.D., ph.D., and Dietrich Matern, M.D.

ANALYSIS OF AMINO ACIDS

Amino acids are quantitatively measured in plasma, urine, and cerebrospinal fluid (CSF) using a variety of techniques that include capillary electrophoresis, gas-liquid chromatography, reversed phase high-performance liquid chromatography (HPLC),[6] ion-exchange liquid chromatography,[5] and tandem mass spectrometry (MS/MS) (see Chapters 5, 6, 7, and 20).[1] Currently, ion-exchange chromatography analysis of amino acids is the most widely used method to identify defects of amino acid metabolism. Screening methods, such as-thin layer chromatography, that do not result in positive identification of all amino acids of clinical interest lead to errors and should be considered obsolete.

Ion-Exchange Liquid Chromatography

Several amino acid analyzers are commercially available. In practice the sample is applied to a column of ion-exchange resin. Buffers of varying pH and ionic strength are pumped through the column at a constant rate. The individual amino acids are retained on the resin depending upon their affinity to the resin. The eluate from the column is mixed with ninhydrin reagent, heated to 135 °C for color development, and monitored with a flow cell photometer at 440 nm (for imino acids) and at 570 nm (for amino acids). The sum of the absorbances at 440 and 570 nm is transferred to a commercial software that stores, calculates, and prints the concentrations of the amino acids in reference to an internal standard. Peak identification is based on retention time, absolute and relative to the nearest internal standard, the 570/440 area ratio, and eventually spiking with the standard solution. Amino acids are quantified by comparing area peak ratios with those of an internal standard.

Sample Requirements

Fasting plasma (heparin) is the preferred specimen type; in newborns and infants, blood should be collected immediately before the next scheduled feeding. Serum is generally derived from blood left to clot at room temperature, a process that leads to artifacts from deamination, loss of sulfur-containing amino acids caused by protein binding, conversion of arginine to ornithine by red blood cell arginase, and release of oligopeptides. Hemolyzed specimens show higher concentrations of amino acids, which are found in higher concentration in blood cells (taurine, aspartic acid, and glutamic acid).

Analysis of urine is indicated for the diagnosis of disorders affecting renal transport of one or more amino acids. Urine collection should avoid fecal contamination and the addition of preservatives. Although a 24-hour collection (kept refrigerated during collection) is necessary in a few clinical circumstances, it is rarely needed during the diagnostic work-up of a patient, and should be avoided when a patient is acutely ill, especially when of pediatric age. Urine creatinine is used for normalization, and the concentration ratio to creatinine is widely used in clinical practice. One potential problem could be encountered in the evaluation of patients with unrecognized disorders of creatine metabolism[2,3,7] in whom a low creatinine excretion leads to quantitative results suggestive of a generalized amino aciduria that is out of proportion with the magnitude of changes observed by visual inspection of the chromatogram. CSF must be collected free of blood contamination.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

Reagents

1. 10% ethanol ("solvent")
2. Li-A Buffer (Beckman #338063)
3. Li-D Buffer (Beckman #338066)
4. Li-E Buffer (Beckman #338067)
5. Li-F Buffer (Beckman #338068)
6. Nin-Rx reagent, 6300 Beckman #338069; supplied as two components (liquid and additive) to be mixed for 2 hours at room temperature before use
7. Li-R, 6300 regeneration buffer (Beckman #338086)
8. Li-S, sample dilutor, pH 2.2 (Beckman #338084)
9. Stock internal standard solution 2.0 mmol/L aminoethylcysteine (FLUKA #06678), 1.0 mmol/L glucosaminic acid (FLUKA #9132) in lithium citrate diluting buffer, Li-S, pH 2.2
10. Working sample dilutor for physiological fluids 400 mL of Beckman Li-S from pH 2.2 to pH 1.0 with concentrated HCl
11. Calibrated stock standards
    B+ (physiological standard #338157), 2.5 mol/mL of 0.1 mol/L HCl
    AN+ (acidics and neutrals standard #338156), 2.5 mol/mL of 0.1 mol/L HCl
    STD (physiological standard #338088), 2.5 mol/mL of 0.1 mol/L HCl
    Asparagine (General Biochemicals Corp. #55698), 1.25 mol/mL of 0.1 mol/L HCl
    Glutamine (General Biochemicals Corp. #57476), 1.25 mmol/mL of 0.1 mol/L HCl
    Tryptophan (General Biochemicals Corp. #52645), 2.5 mmol/mL of 0.1 mol/L HCl
12. Working Standard: 1 mL each of AN+, B+, and STD standards, plus asparagine (ASN), glutamine (GLN), and tryptophan (TRP) stock standards, 350 µL of 3 mol/L LiOH, diluted to 10 mL with Li-S pH 2.2 sample dilutor

Sample Preparation

A predetermined urine volume (equivalent to 0.1 mg of creatinine, 1 mL if creatinine is <10 mg/dL) is mixed with Li-S sample dilutor (pH 2.2) to give a creatinine concentration of 0.1 mg/mL. Two hundred and fifty µL of normalized urine, plasma, or CSF are mixed with an equal volume of internal standard solution (aminoethylcysteine 400 µmol/L and glucosaminic acid 200 µmol/L in Li-S, pH 2.2) and filtered through an Amicon Centrifree micropartition system by spinning at 4000 RPM for 5 minutes at +4 °C. Prepared samples are placed in individual sampling loops unique to the amino acid analyzer.

Reference Intervals

In our laboratory, age-matched reference intervals for urine and plasma amino acids are from Shapira et al.[4]

ANALYSIS OF ORGANIC ACIDS

Sample Requirements

Organic acids (OA) are extracted from urine by liquid-liquid extraction. A volume of a random urine specimen corresponding to 0.25 mg of creatinine is used. For very dilute urine specimens (creatinine <8 mg/dL), the amount aliquoted is equal to 3 mL, and a correction factor is applied appropriately.

Reagents

1. Pentadecanoic acid (Sigma P-6125), internal standard, 1 mg/mL in methanol
2. N,O,-bis-(trimethylsilyl)trifluoroacetamide with 1% trimethylchlorosilane (BSTFA/1% TMCS) Pierce # 38831 J
3. 6 mol/L NaOH
4. 6 mol/L HCl
5. Ethyl acetate, HPLC grade
6. Na_2SO_4 anhydrous
7. Methanol, HPLC grade
8. 2.5% Hydroxylamine-HCl
9. Sodium chloride

Sample Preparation

Urine samples normalized to creatinine concentration are first mixed with the internal standard solution (100 µL). If

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

stabilization of 2-keto acids (oximation) is required, pH is adjusted to 7.0 with 30% NaOH before the addition of 0.5 mL of hydroxylamine hydrochloride and allowed to react for 30 minutes in a water bath at 60 °C. Capped tubes are cooled at room temperature. One gram of NaCl and 250 µL of 6 mol/L HCl are added to each tube. After verification that the pH is <2.0, 2.5 mL of ethyl acetate are added and mixed vigorously before centrifugation for 1 minute. The top phase (ethyl acetate) is transferred to another tube using a Pasteur pipette; the extraction is repeated three more times. The combined solvent phases are dried over 1 g of Na_2SO_4 and transferred to a third tube. The ethyl acetate is evaporated just to dryness in a water bath at 60 °C under a gentle stream of nitrogen. After evaporation, organic acids present in the dry residue are converted to their corresponding trimethylsilyl (TMS) ethers by addition of 100 µL of BSTFA/1%TMCS and allowed to react in a heating block for 30 minutes at 80 °C. After cooling at room temperature, specimens ready for analysis are transferred to autosampler vials.

Capillary Gas Chromatography-Mass Spectrometry

The organic acid-TMS ethers are separated in a capillary gas chromatography (GC) column containing an immobilized nonpolar stationary phase. Organic acids are detected by electron impact (EI) mass spectrometry performed in the scan mode m/z 50 to 550 to obtain mass spectra. Identification is by comparison with a library of spectra generated by analysis of pure standard compounds integrated by published spectra, when applicable. A commercially available bench-top GC-MS system with autosampler (Agilent 6890/5973 or equivalent) is suitable. The GC column is cross-linked with 5% phenyl (poly)methyl silicone, 25 m; internal diameter 0.20 mm; stationary phase film thickness 0.33 µm (Agilent HP-5, DB-5 or equivalent). Chromatographic conditions: injector temperature 250 °C, initial temperature 80 °C (hold time 4 minutes.), ramp rate 8 °C/min to a final temperature of 290 °C (hold time 2.75 minutes; total run time 33 minutes).

Reference Intervals

Age-matched reference intervals of selected organic acids and acylglycines are listed in Table 55-5 of Chapter 55 of the 4th edition of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*.

ANALYSIS OF ACYLCARNITINES

Quantitative acylcarnitine profiling by MS/MS plays a critical role in every clinical application of biochemical genetics: prenatal diagnosis, newborn screening, evaluation of symptomatic patients, and postmortem screening. As with other complex metabolic profiles, it is critical to complement analytical proficiency with in-depth interpretation of results and informative reporting.

Sample Requirements

Carnitine and its esters are physiologically present in all biological fluids. For diagnostic purposes, acylcarnitines were first measured in urine[3] until plasma and/or serum became the preferred specimen types in diagnostic settings,[2,8] and blood dried on filter paper for newborn screening.[1] However, urinalysis could be valuable in the investigation of patients with inconclusive and/or borderline urine organic acid and plasma acylcarnitine profiles and useful in the selection of further in vitro investigations.[6] Bile is analyzed postmortem in the evaluation of cases of sudden and unexpected death.[4] Cell-free supernatant of amniotic fluid is used for the prenatal diagnosis of selected inborn errors of metabolim (IEM).[5,7] All sample types, with the exception of blood and bile spots dried on filter paper, which can be sent at room temperature, should be kept frozen until analysis. Long-term storage at room temperature causes progressive losses; degradation of short-chain acylcarnitines happens faster than long-chain species.

Reagents

1. Acetyl-d_3-carnitine, propionyl-d_3-carnitine, butyryl-d_3-carnitine, octanoyl-d_3-carnitine, dodecanoyl-d_3-carnitine, and palmitoyl-d_3-carnitine (acquired from Dr. Herman J. ten Brink, Klinische Genetica, Amsterdam)
2. 3M/L HCl in n-butanol, (#201009; Regis Chemical Co., Morton Grove, Ill.)
3. Methanol, HPLC grade
4. 80% acetonitrile:water
5. Nitrogen gas scrubbed with BHT-1 hydrocarbon trap (Chromtech, Apple Valley, Minn.)

Sample Preparation

Plasma, serum bile, amniotic fluid: 20 µL

Urine: 20 µL of a volume equivalent to 0.25 mg of creatinine diluted to 300 µL; no dilution is performed if creatinine concentration is <9 mg/dL

Blood, bile dried spots: one 3/16 inch punch

Specimens as listed above are mixed with 300 µL of a mixture of deuterium-labeled internal standards (see reagents) in methanol. After a brief centrifugation (2 minutes at 13,000 rpm), the supernatant is transferred to a clean tube and evaporated to dryness under a gentle stream of nitrogen at 40 °C. The samples are then derivatized to their butyl esters by addition of 100 µL 3 mol/L HCl in n-butanol and heating at 65 °C for 15 minutes. After a final dry down, samples are reconstituted in 100 µL of 80% Acetonitrile:Water (4:1).

Equipment/Supplies

1. Pierce Reacti-Therm heating module (2)
2. Pierce Reacti-Vap evaporating unit
3. Pierce React-Vial No. 13221, with caps
4. Thermolyne MaxiMix II type 37600 vortex mixer
5. Centrifuge, #3551 X Systems
6. 1.5 mL Micro Tube, Sarstedt, 39 × 10 mm.

Copyright © 2006, 1999, 1994, 1986 Elsevier Inc. All rights reserved.

7. Teflon/rubber laminated disks (Pierce #12412)
8. Autosampler vials (Fisher #0334064) and caps (Fisher #0337749)
9. PE Sciex API 2000 LC/MS/MS with TurboIon Spray APCI electrospray interface source
10. PE Series 200 isocratic LC pump
11. PE Series 200 LC autosampler with 100 position sample tray insert
12. 0.5 U peek filter end fitting, Chromtech A-428X
13. 0.5 U filters, Chromtech A-431
14. Back pressure column, BDS Hypersil C18, 3 m, 50 × 1 (#053-46-1; Keystone Scientific)

Electrospray Tandem Mass Spectrometry

With electrospray ionization tandem mass spectrometry (ESI-MS/MS), the liquid sample is introduced into the ion source through a capillary tube and exposed to a strong electric field and a counter flow of nitrogen gas, which in combination produce the electrospray (see Chapter 7). The solvent evaporates and eventually desorption of charged ions occurs into the mass analyzer. ESI occurs under atmospheric pressure, allowing efficient ionization, and the mass analyzers operate at very low pressure. The combination is possible by introducing the ions into the analyzers through a very small orifice (<1 mm) and using powerful vacuum pumps.

A data file is generated for all ions with precursors of m/z 85 within a mass range of m/z 250 to 500. Profiling of acylcarnitines as $[M+H]^+$ molecular ions allows identification, automated calculation of quantitative and semiquantitative concentrations for each acylcarnitine species against the internal standards, and comparison with age-appropriate reference intervals.

LC Operating Parameters

PE Series 200 LC pump operating isocratic using 80% acetonitrile:water at 0.04 mL per minute (40 µL/min). Back pressure is provided by a 50 × 1-mm C18 column (Keystone) between the pump and autosampler.

PE Series 200 LC Autosampler operating under external control is controlled by vendor software. The syringe/system flush solutions are the 80% acetonitrile:water used as mobile phase. The autosampler is connected directly to the MS/MS TurboIon Spray source. The injected amount is 20 µL.

0.5 U Peek filter is installed between the autosampler and TurboIon Spray APCI electrospray interface source. The filter end fitting is discarded and replaced after approximately 200 injections.

Reference Intervals

Acylcarnitine reference intervals in use in the laboratory of the authors are shown for plasma in Table 55-6, for urine in Table 55-7, and for postmortem blood and bile in Table 55-8 of Chapter 55 of the 4th edition of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*.

Whole blood 3-hydroxyoctadecadienoylcarnitine, 2277*t*
Whole blood 3-hydroxyoctadecanoylcarnitine, 2277*t*
Whole blood 3-hydroxyoctadecenoylcarnitine, 2277*t*
Whole blood 3-hydroxytetradecanoylcarnitine, 2278*t*
Whole blood 3-hydroxytetradecenoylcarnitine, 2279*t*
Whole blood isobutyrylcarnitine, 2280*t*
Whole blood isovaleryl/CH3 butyrylcarnitine, 2281*t*
Whole blood lactate, 878, 2282*t*
Whole blood lead, 2282*t*
Whole blood malonylcarnitine, 2284*t*
Whole blood manganese, 2284*t*
Whole blood mercury, 2284*t*
Whole blood methanol, 2285-2286*t*
Whole blood methemoglobin, 2286*t*
Whole blood methylmalonylcarnitine, 2286*t*
Whole blood nickel, 2287*t*
Whole blood octadecadienoylcarnitine, 2287*t*
Whole blood octadecanoylcarnitine, 2287*t*
Whole blood octadecenoylcarnitine, 2288*t*
Whole blood octanoylcarnitine, 2288*t*
Whole blood octenoylcarnitine, 2288*t*
Whole blood phenylalanine, 2290*t*
Whole blood propionylcarnitine, 2292*t*
Whole blood pyruvate, 878
Whole blood pyruvic acid, 2293*t*
Whole blood selenium, 2294*t*
Whole blood serotonin, 2294*t*
Whole blood tetradecadienoylcarnitine, 2296*t*
Whole blood tetradecanoylcarnitine, 2296*t*
Whole blood tetradecenoylcarnitine, 2296*t*
Whole blood thallium, 2297*t*
Whole blood thyroid-stimulating hormone, 2297*t*
Whole blood tiglylcarnitine, 2299*t*
Whole blood tube additives, 44*t*
Whole blood vitamin B_1, 2302*t*
Whole blood vitamin B_3, 2289*t*
Whole genome and whole transcriptome amplification, 1419
Wick flow, 122
Wide-bandpass filter in spectrophotometry, 67, 67*f*
Wilcoxon statistic, ROC curve and, 413
Wild type of p53 gene, 784
Wiley-McLaren instruments, 175
Wilms' tumor, 784-785
Wilson's disease, 1120, 1128
acute, 1808
ceruloplasmin and, 557, 558
hepatic damage in, 1815-1816
laboratory features of, 1805*t*
Withdrawal syndrome, 1292
Workcell, 282, 282*f*
Workplace drug testing, 1318
Workstation, 281
WT1 gene, 784-785

X

X-linked CPS deficiency, 2214-2215*t*
X-linked diseases, 1496-1502
dominant hypophosphatemic rickets in, 1710
Duchenne's muscular dystrophy in, 1498-1500
fragile X syndrome in, 1500*f,* 1500-1501, 1502*f*
glyceroluria in, 2228-2229*t*
hemophilia A in, 1496-1498, 1498*f*
ornithine transcarbamoylase deficiency in, 2220
recessive nephrolithiasis in, 1710
Xanax. *See* Alprazolam.
Xenobiotics, hepatic clearance of, 1791-1792
Xenon lamp in fluorometry, 78
Xerophthalmia in vitamin A deficiency, 1083
Xylidyl blue, 1911, 1911*f*
Xylocaine. *See* Lidocaine.

Y
Y-chromosome markers, 1542-1543, 1543*t*
Yocto, metric prefix of SI unit, 7*t*
Yolk sac, 2153
Yotta, metric prefix of SI unit, 7*t*

Z
Z-spray, 168
Z-test, 508-509
Zalcitabine, 1269*t,* 2315*t*
Zarontin. *See* Ethosuximide.
Zeeman correction method, 74
Zellweger's syndrome, 1786
Zepto, metric prefix of SI unit, 7*t*
Zero-order kinetics, 1246
Zeta potential, 127
Zetta, metric prefix of SI unit, 7*t*
Zidovudine, 1269*t,* 2316*t*
Zinc, 1137-1141, 1139*f*
  as causative factor in medical conditions, 1372*t*
  in inhibition of copper absorption, 1120
  oral and intravenous intakes of, 1076*t*
  reference intervals for, 2302*t*
  retinol-binding protein and, 563
  special collection and storage conditions for, 55*t*
  urine specimen preservatives and, 51*t*
Zinc metalloenzymes, 1138-1139
Zinc-protoporphyrin
  lead toxicity and, 1220
Zinc-protoporphyrin *(Continued)*
  qualitative determination of, 1226
  values during pregnancy, 2158*t*
Zollinger-Ellison syndrome, 1877
Zoloft. *See* Sertraline.
Zone electrophoresis, 121
Zonegran. *See* Zonisamide.
Zonisamide, 1250*t,* 1255, 2316*t*
ZPP. *See* Zinc-protoporphyrin.
Zwitterion, 121
Zyban. *See* Bupropion.
Zygote, 2153
Zymogens, 622, 623
Zymography, 763
Zyprexa. *See* Olanzapine.
